This work is provided "as is," and the publisher disclaims any and all warranties, express or implied, including any warranties as to accuracy, comprehensiveness, or currency of the content of this work.

This work is no substitute for individual patient assessment based upon healthcare professionals' examination of each patient and consideration of, among other things, age, weight, gender, current or prior medical conditions, medication history, laboratory data and other factors unique to the patient. The publisher does not provide medical advice or guidance and this work is merely a reference tool. Healthcare professionals, and not the publisher, are solely responsible for the use of this work including all medical judgments and for any resulting diagnosis and treatments.

Given continuous, rapid advances in medical science and health information, independent professional verification of medical diagnoses, indications, appropriate pharmaceutical selections and dosages, and treatment options should be made and healthcare professionals should consult a variety of sources. When prescribing medication, healthcare professionals are advised to consult the product information sheet (the manufacturer's package insert) accompanying each drug to verify, among other things, conditions of use, warnings and side effects and identify

any changes in dosage schedule or contraindications, particularly if the medication to be administered is new, infrequently used or has a narrow therapeutic range. To the maximum extent permitted under applicable law, no responsibility is assumed by the publisher for any injury and/or damage to persons or property, as a matter of products liability, negligence law or otherwise, or from any reference to or use by any person of this work.

Dedication

The editors wish to express their sincere thanks to Dr. Mary Anne Koda-Kimble and Dr. Lloyd Young who created Applied Therapeutics, the gold standard textbook used in the teaching of patient-centered drug therapeutics. Their vision and legendary contributions have inspired generations of health profession students, faculty, and clinicians. We are grateful to the past editors and current editorial team and contributors, as well as faculty colleagues and clinicians across the globe for their tremendous dedication to their patients and their communities. They have shaped and inspired the next generation of health care professionals through innovative teaching, mentoring, and dissemination of their scholarship. Finally, we wish to thank our families for their patience and understanding as we embarked on this journey and completed this eleventh edition of the textbook.

Preface

It has been over forty years since the first edition of Applied Therapeutics: The Clinical Use of Drugs was published, and the landscape of health care has changed dramatically. While we have seen tremendous scientific and technologic advancements transform personalized medicine, we also realize the significant challenges that we face within our increasingly complex health care delivery system. More than ever, we are in need of health professionals who are able to think critically and to utilize problem-solving skills to improve patient outcomes. Approximately four decades later, the founding principle for this textbook—a patient-centric, case-based approach to learning—remains the cornerstone of health professions education. Our authors present approximately 900 patient cases that stimulate the reader to integrate and apply therapeutic principles in the context of specific clinical situations. Health profession students and practitioners gain a glimpse into the minds of clinicians as they work to assess and solve therapeutic problems and develop their own critical-thinking and problem-solving skills.

Readers familiar with past editions of the book will notice that the overall design of the book is consistent with the tenth edition, which incorporates a Core Principles section at the beginning of each chapter, providing the most important "take home" information from the chapter. Each Core Principle is mapped to specific cases within the chapter where the principle is discussed in detail. Key references and websites are listed at the end of each chapter, whereas the full reference lists for each chapter have been moved online.

Building upon the excellent foundation of case-based learning provided in previous editions, the eleventh edition has incorporated changes to meet the evolving educational needs of health profession educators and students across the globe. The editors and contributors have utilized the five Institute of Medicine (IOM) core competencies as a broad framework for proposing case studies and questions within the textbook: patient-centered care; interdisciplinary teams; evidence-based practice; quality improvement; and informatics. In addition, the Accreditation Council for Pharmacy Education (ACPE) Accreditation Standards 2016, the Center for the Advancement of Pharmacy Education (CAPE) Educational Outcomes, and the North American Pharmacist Licensure Examination (NAPLEX) revised competency statements have served as road maps for the editorial team and contributors in designing the eleventh edition.

Featuring contributions from more than 200 experienced clinicians, every chapter has been revised and updated to reflect our ever-changing knowledge of drugs and the application of this knowledge to the individualized therapy of patients. Content within several sections has been extensively reorganized, with new chapters introduced to expand important topics. Among these are seven new chapters within the General Principles, Immunologic Disorders, Rheumatic and Musculoskeletal Diseases, Neurologic Disorders, Psychiatric Disorders & Substance Abuse, and Hematology and Oncology sections. Of particular note are featured new chapters in the General Principles section on Drug Interactions, Pharmacogenomics and Personalized Medicine, and Interprofessional Education and Practice. In addition, a chapter has been redesigned to focus on Care of the Critically Ill Adult, which now complements the chapter on Care of the Critically Ill Child.

Given the importance of incorporating Interprofessional Education (IPE) within the didactic, practicum, and clinical settings, we have added an array of IPE case studies prepared by contributors that are representative of various sections of the textbook. These IPE cases, along with answer guides, will be available for instructors on the textbook's website (see the "Additional Resources" section).

We welcome your feedback as we undertake planning for the next edition. The authors have drawn on information from the literature, current standards, and their own clinical experiences to share the process involved in making sound and thoughtful therapeutic decisions. However, it remains the responsibility of every practitioner to evaluate the appropriateness of a particular opinion in the context of the actual clinical situation, bearing in mind any recent developments in the field. We strongly urge students and practitioners to consult several appropriate information sources when working with new and unfamiliar drugs.

Acknowledgments

We are deeply indebted to the many dedicated people who have given of themselves to complete the eleventh edition of Applied Therapeutics: The Clinical Use of Drugs. We are grateful to our contributing authors who have worked tirelessly to provide the highest quality of work, while balancing numerous responsibilities as educators, clinicians, and researchers. We are grateful for the exceptional work of our twenty-six section editors, who provided critical feedback necessary both in the organizational structure of the textbook and in the individual editing of chapters; without their dedication and support, this edition would not be possible. In particular, we wish to recognize those returning section editors as they have been a guiding force for the eleventh edition: Drs. Jean M. Nappi, Timothy J. Ives, Marcia L. Buck, Judith L. Beizer, and Myrna Y. Munar. We sincerely thank the past editorial team of Applied Therapeutics, with special thanks to Dr. Brian K. Alldredge and Dr. B. Joseph Guglielmo for their guidance and support and contributions to the eleventh edition. We would also like to thank Facts and Comparisons for allowing us to use their data for the construction of some of our tables.

The team from Wolters Kluwer, Matt Hauber, Andrea Vosburgh, and Annette Ferran, deserve special recognition for their efforts. Their exceptional patience, attention to detail, and guidance have been critical to the success of this project. We sincerely thank Tara Slagle (project management) and Samson Premkumar (production) for their assistance in completing this edition. Most importantly, we wish to acknowledge the love, understanding, and unwavering support of our spouses and families. They selflessly gave to us early mornings, late nights, weekends, and vacation time that we spent writing and editing.

Consistent with past editions, we continue to dedicate our work to our students who inspire us and to the many patients we have been privileged to care for and who have taught us invaluable lessons. We also dedicate the eleventh edition to those clinicians and educators who have served as pioneering leaders and role models in the delivery of patient-centered care using team-based approaches.

Additional Resources

The eleventh edition of Applied Therapeutics: The Clinical Use of Drugs includes additional resources for both instructors and students, available on the book's companion website at **http://thepoint.lww.com/AT11e**.

STUDENT RESOURCES

Students who have purchased Applied Therapeutics: The Clinical Use of Drugs, Eleventh Edition have access to the following additional resources for each chapter:

- A full online reference list for that chapter

INSTRUCTOR RESOURCES

Approved adopting instructors will be given access to the following additional resources:

- Interprofessional Education (IPE) Case Studies and Answer Guides
- Each chapter will map which NAPLEX competency statements are addressed with it, which will be a helpful resource for instructors.

Central Alabama Veterans Health Care System
Montgomery, Alabama

Timothy R. Hudd, PharmD, AE-C
Associate Professor of Pharmacy Practice
School of Pharmacy–Boston
MCPHS University
Boston, Massachusetts

Bethany Ibach, PharmD, BCPPS
Assistant Professor of Pharmacy Practice
School of Pharmacy, Pediatrics Division
Texas Tech University Health Sciences Center
Abilene, Texas

Gail S. Itokazu, PharmD
Clinical Associate Professor
Department of Pharmacy Practice

University of Illinois, Chicago
Clinical Pharmacist
Division of Infectious Diseases
John H. Stroger Jr. Hospital of Cook County
Chicago, Illinois

Timothy J. Ives, PharmD, MPH, FCCP, CPP

Professor of Pharmacy
Adjunct Professor of Medicine
Eshelman School of Pharmacy
University of North Carolina at Chapel Hill
Chapel Hill, North Carolina

Nicole A. Kaiser, RPh, BCOP

Oncology Clinical Pharmacy Specialist
Children's Hospital Colorado
Aurora, Colorado

James S. Kalus, PharmD, FASHP

Director of Pharmacy
Henry Ford Health System
Henry Ford Hospital
Detroit, Michigan

Marina D. Kaymakcalan, PharmD

Clinical Pharmacy Specialist
Dana Farber Cancer Institute
Boston, Massachusetts

Michael B. Kays, PharmD, FCCP

Associate Professor
Department of Pharmacy Practice
Purdue University College of Pharmacy
West Lafayette and Indianapolis, Indiana

Jacob K. Kettle, PharmD, BCOP

Oncology Clinical Pharmacy Specialist
University of Missouri Health Care
Columbia, Missouri

Rory E. Kim, PharmD

Assistant Professor of Clinical Pharmacy
University of Southern California School of Pharmacy
Los Angeles, California

Lee A. Kral, PharmD, BCPS, CPE

Clinical Pharmacy Specialist, Pain Management
Department of Pharmaceutical Care
The University of Iowa Hospitals and Clinics
Iowa City, Iowa

Donna M. Kraus, PharmD, FAPhA, FPPAG, FCCP
Pediatric Clinical Pharmacist/Associate Professor of Pharmacy Practice
Departments of Pharmacy Practice and Pediatrics
Colleges of Pharmacy and Medicine
University of Illinois at Chicago
Chicago, Illinois

Susan A. Krikorian, MS, PharmD
Professor of Pharmacy Practice
School of Pharmacy–Boston

MCPHS University
Boston, Massachusetts

Andy Kurtzweil, PharmD, BCOP
Pharmacy Supervisor–Adult Hematology and Oncology/BMT
University of Minnesota Health
Minneapolis, Minnesota

Benjamin Laliberte, PharmD, BCPS
Clinical Pharmacy Specialist, Cardiology
Massachusetts General Hospital
Boston, Massachusetts

Jerika T. Lam, PharmD, AAHIVP
Assistant Professor of Pharmacy Practice
School of Pharmacy
Chapman University
Irvine, California

Trisha LaPointe, PharmD, BCPS
Associate Professor of Pharmacy Practice
School of Pharmacy–Boston
MCPHS University
Boston, Massachusetts

Alan H. Lau, PharmD
Professor
Director, International Clinical Pharmacy Education
College of Pharmacy
University of Illinois at Chicago
Chicago, Illinois

Elaine J. Law, PharmD, BCPS
Assistant Clinical Professor of Pharmacy Practice
Thomas J. Long School of Pharmacy and Health Sciences

University of the Pacific
Stockton, California

Kimberly Lenz, PharmD

Clinical Pharmacy Manager
Office of Clinical Affairs
University of Massachusetts Medical School
Quincy, Massachusetts

Russell E. Lewis, PharmD, FCCP

Associate Professor of Medicine, Infectious Diseases
Department of Medical and Surgical Services
Infectious Diseases Unit, Policlinico S. Orsola-Malpighi
University of Bologna
Bologna, Italy

Rachel C. Long, PharmD, BCPS

Clinical Staff Pharmacist
Carolinas HealthCare System
Charlotte, North Carolina

Ann M. Lynch, BSP, PharmD, AE-C

Professor of Pharmacy Practice
School of Pharmacy–Worcester/Manchester
MCPHS University
Worcester, Massachusetts

Matthew R. Machado, PharmD

Associate Professor of Pharmacy Practice
School of Pharmacy–Boston
MCPHS University
Boston, Massachusetts

Emily Mackler, PharmD, BCOP

Clinical Pharmacist and Project Manager
Michigan Oncology Quality Consortium
University of Michigan
Ann Arbor, Michigan

Daniel R. Malcolm, PharmD, BCPS, BCCCP

Associate Professor and Vice-Chair
Clinical and Administrative Services
Sullivan University College of Pharmacy
Louisville, Kentucky

Shannon F. Manzi, PharmD, NREMT, FPPAG

Director, Clinical Pharmacogenomics Service
Manager, Emergency and ICU Pharmacy Services
Boston Children’s Hospital
Boston, Massachusetts

Joel C. Marrs, PharmD, FCCP, FASHP, FNLA, BCPS-AQ Cardiology, BCACP, CLS, ASH-CHC
Associate Professor
Department of Clinical Pharmacy
University of Colorado Anschutz Medical Campus
Skaggs School of Pharmacy and Pharmaceutical Sciences
Clinical Pharmacy Specialist
Department of Pharmacy
Denver Health and Hospital Authority
Aurora, Colorado

John Marshall, PharmD, BCPS, BCCCP, FCCM
Clinical Pharmacy Coordinator–Critical Care
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Darius L. Mason, PharmD, BCPS, FACN
Clinical Pharmacist
Methodist South Hospital
Memphis, Tennessee

Susan L. Mayhew, PharmD, BCNSP, FASHP
Professor and Dean
Appalachian College of Pharmacy
Oakwood, Virginia

James W. McAuley, RPh, PhD, FAPhA
Associate Dean for Academic Affairs and Professor
Departments of Pharmacy Practice and Neurology
The Ohio State University College of Pharmacy
Columbus, Ohio

Sarah E. McBane, PharmD, CDE, BCPS, FCCP, FCPhA, APh
Professor and Chair
Department of Pharmacy Practice
West Coast University
Los Angeles, California

William W. McCloskey, BA, BS, PharmD
Professor of Pharmacy Practice
School of Pharmacy–Boston
MCPHS University
Boston, Massachusetts

Chephra McKee, PharmD
Assistant Professor of Pharmacy Practice
School of Pharmacy
Pediatrics Division
Texas Tech University Health Sciences Center
Abilene, Texas

Molly G. Minze, PharmD, BCACP
Associate Professor of Pharmacy Practice
Ambulatory Care Division
School of Pharmacy
Texas Tech University Health Sciences Center
Abilene, Texas

Amee D. Mistry, PharmD
Associate Professor Pharmacy Practice
School of Pharmacy–Boston
MCPHS University
Boston, Massachusetts

Katherine G. Moore, PharmD, BCPS, BCACP
Executive Director of Experiential Education
Associate Professor of Pharmacy Practice
Presbyterian College School of Pharmacy
Clinton, South Carolina

Jill A. Morgan, PharmD, BCPS, BCPPS
Associate Professor and Chair
Department of Pharmacy Practice and Science
University of Maryland School of Pharmacy
Baltimore, Maryland

Anna K. Morin, PharmD
Professor of Pharmacy Practice and Dean
School of Pharmacy–Worcester/Manchester
MCPHS University
Worcester, Massachusetts

Pamela B. Morris, MD, FACC, FAHA, FASPC, FNLA
Director, Seinsheimer Cardiovascular Health Program
Co-Director, Women’s Heart Care
Medical University of South Carolina
Charleston, South Carolina

Oussayma Moukhachen, PharmD, BCPS
Assistant Professor Pharmacy Practice
School of Pharmacy–Boston
MCPHS University
Boston, Massachusetts
Clinical Care Specialist
Mount Auburn Hospital
Cambridge, Massachusetts

Kelly A. Mullican, PharmD
Primary Care Clinical Pharmacy Specialist
Kaiser Permanente–Mid-Atlantic States
Washington, District of Columbia

Myrna Y. Munar, PharmD
Associate Professor of Pharmacy
College of Pharmacy
Oregon State University
Oregon Health and Science University
Portland, Oregon

Yulia A. Murray, PharmD, BCPS
Assistant Professor of Pharmacy Practice
School of Pharmacy–Boston
MCPHS University
Boston, Massachusetts

Milap C. Nahata, MS, PharmD, FCCP, FAPhA, FASHP
Director, Institute of Therapeutic Innovations and Outcomes
Professor Emeritus of Pharmacy, Pediatrics, and Internal Medicine
Colleges of Pharmacy and Medicine
The Ohio State University
Columbus, Ohio

Richard S. Nicholas, PharmD, ND, CDE, BCPS, BCACP
Assistant Professor of Pharmacy Practice
Appalachian College of Pharmacy
Oakwood, Virginia

Stefanie C. Nigro, PharmD, BCACP, BC-ADM
Assistant Professor of Pharmacy Practice
School of Pharmacy–Boston
MCPHS University
Boston, Massachusetts

Cindy L. O’Bryant, PharmD, BCOP, FCCP, FHOPA
Professor
Department of Clinical Pharmacy
Skaggs School of Pharmacy and Pharmaceutical Sciences
Clinical Pharmacy Specialist in Oncology
University of Colorado Cancer Center
Aurora, Colorado

Kirsten H. Ohler, PharmD, BCPS, BCPPS
Clinical Assistant Professor of Pharmacy Practice
College of Pharmacy
University of Illinois at Chicago
Clinical Pharmacy Specialist–Neonatal ICU
University of Illinois at Chicago Hospital and Health Sciences System

Chicago, Illinois

Julie L. Olenak, PharmD
Assistant Dean of Student Affairs
Associate Professor
Department of Pharmacy Practice
Nesbitt College of Pharmacy and Nursing
Wilkes University
Wilkes-Barre, Pennsylvania

Jacqueline L. Olin, MS, PharmD, BCPS, CDE, FASHP, FCCP
Professor of Pharmacy
School of Pharmacy
Wingate University
Wingate, North Carolina

Neeta Bahal O'Mara, PharmD, BCPS
Clinical Pharmacist
Dialysis Clinic, Inc.
North Brunswick, New Jersey

Robert L. Page, II, PharmD, MSPH, FHFSA, FCCP, FASHP, FASCP, CGP, BCPS (AQ-Cards)
Professor
Departments of Clinical Pharmacy and Physical Medicine
School of Pharmacy and Pharmaceutical Sciences
University of Colorado
Aurora, Colorado

Louise Parent-Stevens, PharmD, BCPS
Assistant Director of Introductory Pharmacy Practice Experiences
Clinical Assistant Professor
Department of Pharmacy Practice
University of Illinois at Chicago College of Pharmacy
Chicago, Illinois

Dhiren K. Patel, PharmD, CDE, BC-ADM, BCACP
Associate Professor of Pharmacy Practice
School of Pharmacy–Boston
MCPHS University
Boston, Massachusetts

Katherine Tipton Patel, PharmD, BCOP
Clinical Pharmacy Specialist
The University of Texas
MD Anderson Cancer Center
Houston, Texas

Jennifer T. Pham, PharmD, BCPS, BCPPS
Clinical Assistant Professor, Department of Pharmacy Practice
University of Illinois at Chicago College of Pharmacy
Clinical Pharmacy Specialist, Neonatal Clinical Pharmacist
University of Illinois Hospital and Health Sciences System
Chicago, Illinois

Jonathan D. Picker, MBChB, PhD
Assistant Professor
Harvard Medical School
Clinical Geneticist
Boston Children's Hospital
Boston, Massachusetts

Brian A. Potoski, PharmD, BCPS
Associate Professor
Departments of Pharmacy and Therapeutics
University of Pittsburgh School of Pharmacy
Associate Director, Antibiotic Management Program
University of Pittsburgh Medical Center
Presbyterian University Hospital
Pittsburgh, Pennsylvania

David J. Quan, PharmD, BCPS
Health Sciences Clinical Professor of Pharmacy
Department of Clinical Pharmacy
School of Pharmacy
University of California, San Francisco
Pharmacist Specialist–Solid Organ Transplant
University of California, San Francisco Medical Center
San Francisco, California

Erin C. Raney, PharmD, BCPS, BC-ADM
Professor of Pharmacy Practice
Midwestern University College of Pharmacy–Glendale
Glendale, Arizona

Valerie Relias, PharmD, BCOP
Clinical Pharmacy Specialist
Division of Hematology/Oncology
Tufts Medical Center
Boston, Massachusetts

Lee A. Robinson, MD
Instructor
Department of Psychiatry
Harvard Medical School
Boston, Massachusetts

Associate Training Director
Child and Adolescent Psychiatry Fellowship
Primary Care Mental Health Integrated Psychiatrist
Cambridge Health Alliance
Cambridge, Massachusetts

Charmaine Rochester-Eyeguokan, PharmD, BCPS, BCACP, CDE
Associate Professor of Pharmacy Practice and Science
University of Maryland School of Pharmacy
Baltimore, Maryland

Carol J. Rollins, PharmD, MS, RD, CNSC, BCNSP
Clinical Associate Professor
Department of Pharmacy Practice and Science
College of Pharmacy
The University of Arizona
Tucson, Arizona

Melody Ryan, PharmD, MPH, GCP, BCPS
Professor
Department of Pharmacy Practice and Science
College of Pharmacy
University of Kentucky
Lexington, Kentucky

David Schnee, PharmD, BCACP
Associate Professor of Pharmacy Practice
School of Pharmacy–Boston
MCPHS University
Boston, Massachusetts

Eric F. Schneider, BS Pharm, PharmD
Assistant Dean for Academics
Professor
School of Pharmacy
Wingate University
Wingate, North Carolina

Sheila Seed, PharmD, MPH
Professor of Pharmacy Practice
School of Pharmacy–Worcester/Manchester
MCPHS University
Worcester, Massachusetts

Timothy H. Self, PharmD
Professor of Clinical Pharmacy
College of Pharmacy
University of Tennessee Health Science Center
Memphis, Tennessee

Amy Hatfield Seung, PharmD, BCOP
Senior Director of Clinical Development
Physician Resource Management/Caret
Cary, North Carolina

Nancy L. Shapiro, PharmD, FCCP, BCPS
Operations Coordinator
University of Illinois Hospital and Health Sciences System
Clinical Associate Professor of Pharmacy Practice
Director, PGY2 Ambulatory Care Residency
College of Pharmacy
University of Illinois at Chicago
Chicago, Illinois

Iris Sheinhait, PharmD, MA, RPh
Certified Poison Information Specialist
Adjunct Assistant Professor
Regional Center for Poison Control Serving Massachusetts and Rhode Island
Boston Children's Hospital and MCPHS University
Boston, Massachusetts

Greene Shepherd, PharmD, DABAT
Clinical Professor and Vice-Chair
Division of Practice Advancement and Clinical Education
Director of Professional Education, Asheville Campus
Eshelman School of Pharmacy
University of North Carolina at Chapel Hill
Asheville, North Carolina

Devon A. Sherwood, PharmD, BCPP
Assistant Professor
Psychopharmacology
College of Pharmacy
University of New England
Portland, Maine

Richard J. Silvia, PharmD, BCCP
Associate Professor of Pharmacy Practice
School of Pharmacy–Boston
MCPHS University
Boston, Massachusetts

Carrie A. Sincak, PharmD, BCPS, FASHP
Assistant Dean for Clinical Affairs and Professor
Department of Pharmacy Practice
Midwestern University Chicago College of Pharmacy
Downers Grove, Illinois

Harleen Singh, PharmD, BCPS-AQ Cardiology, BCACP
Clinical Associate Professor of Pharmacy Practice
Oregon State University
Oregon Health and Science University
Portland, Oregon

Jessica C. Song, MA, PharmD
Clinical Pharmacy Supervisor
PGY1 Pharmacy Residency Coordinator
Department of Pharmacy Services
Santa Clara Valley Medical Center
San Jose, California

Suellyn J. Sorensen, PharmD, BCPS, FASHP
Director
Clinical Pharmacy Services
St. Vincent Indianapolis
Indianapolis, Indiana

Linda M. Spooner, PharmD, BCPS (AQ-ID), FASHP
Professor of Pharmacy Practice
School of Pharmacy–Worcester/Manchester
MCPHS University
Clinical Pharmacy Specialist in Infectious Diseases
Saint Vincent Hospital
Worcester, Massachusetts

Karyn M. Sullivan, PharmD, MPH
Professor of Pharmacy Practice
School of Pharmacy–Worcester/Manchester
MCPHS University
Worcester, Massachusetts

David J. Taber, PharmD, MS, BCPS
Associate Professor
Division of Transplant Surgery
College of Medicine
Medical University of South Carolina
Charleston, South Carolina

Candace Tan, PharmD, BCACP
Clinical Pharmacist
Kaiser Permanente
Los Angeles, California

Yasar O. Tasnif, PharmD, BCPS, FAST
Associate Professor
Cooperative Pharmacy Program
University of Texas at Austin and University of Texas, Rio Grande Valley
Clinical Pharmacist Specialist

Doctor’s Hospital at Renaissance–Renaissance Transplant Institute
Edinburg, Texas

Daniel J. G. Thirion, BPharm, MSc, PharmD, FCSHP
Professeur Titulaire de Clinique
Faculté de Pharmacie
Université de Montréal
Pharmacien
Centre Universitaire de Santé McGill
Montréal, Québec, Canada

Angela M. Thompson, PharmD, BCPS
Assistant Professor
Department of Clinical Pharmacy
Skaggs School of Pharmacy and Pharmaceutical Sciences
University of Colorado
Aurora, Colorado

Lisa A. Thompson, PharmD, BCOP
Clinical Pharmacy Specialist in Oncology
Kaiser Permanente Colorado
Lafayette, Colorado

Toyin Tofade, MS, PharmD, BCPS, CPCC
Dean and Professor
Howard University College of Pharmacy
Washington, District of Columbia

Tran H. Tran, PharmD, BCPS
Associate Professor
Midwestern University, Chicago College of Pharmacy
Downers Grove, Illinois

Dominick P. Trombetta, PharmD, BCPS, CGP, FASCP
Associate Professor
Department of Pharmacy Practice
Nesbitt School of Pharmacy
Wilkes University
Wilkes-Barre, Pennsylvania

Toby C. Trujillo, PharmD, FCCP, FAHAH, BCPS-AQ Cardiology
Associate Professor
Department of Clinical Pharmacy
Skaggs School of Pharmacy and Pharmaceutical Sciences
University of Colorado
Aurora, Colorado

Sheila K. Wang, PharmD, BCPS (AQ–ID)
Associate Professor of Pharmacy Practice
Chicago College of Pharmacy

Midwestern University
Downers Grove, Illinois
Clinical Pharmacist, Infectious Disease
Program Director, Rush University Medical Center
Chicago, Illinois

Brian Watson, PharmD, BCPS

Pharmacist
University of Maryland Medical System
St. Joseph's Medical Center
Baltimore, Maryland

Kristin Watson, PharmD, BCPS-AQ Cardiology

Associate Professor, Vice-Chair of Clinical Services
University of Maryland School of Pharmacy
Baltimore, Maryland

Lynn Weber, PharmD, BCOP

Clinical Pharmacy Specialist, Oncology/Hematology
Pharmacy Residency Coordinator and PGY-1 Residency Director
Hennepin County Medical Center
Minneapolis, Minnesota

Kellie Jones Weddle, PharmD, BCOP, FCCP, FHOPA

Clinical Professor of Pharmacy Practice
College of Pharmacy
Purdue University
Indianapolis, Indiana

C. Michael White, PharmD, FCP, FCCP

Professor and Head
Department of Pharmacy Practice
School of Pharmacy
University of Connecticut
Storrs, Connecticut

Natalie Whitmire, PharmD, BCPS, BCGP

Pharmacist Specialist
University of California, San Diego Health

Barbara S. Wiggins, PharmD, BCPS, CLS, AACC, FAHA, FCCP, FNLA

Clinical Pharmacy Specialist–Cardiology
Medical University of South Carolina
Charleston, South Carolina

Kristine C. Willett, PharmD, FASHP

Associate Professor of Pharmacy Practice
School of Pharmacy–Worcester/Manchester
MCPHS University
Manchester, New Hampshire

Bradley R. Williams, PharmD, CGP
Professor of Clinical Pharmacy and Clinical Gerontology
School of Pharmacy
University of Southern California
Los Angeles, California

Casey B. Williams, PharmD, BCOP, FHOPA
Director, Center for Precision Oncology
Director, Department of Molecular and Experimental Medicine
Avera Cancer Institute
Sioux Falls, South Dakota

Dennis M. Williams, PharmD, BCPS, AE-C
Associate Professor and Vice-Chair for Professional Education and Practice
Division of Pharmacotherapy and Experimental Therapeutics
Eshelman School of Pharmacy
University of North Carolina at Chapel Hill
Chapel Hill, North Carolina

Katie A. Won, PharmD, BCOP
Clinical Pharmacist
Hennepin County Medical Center
Minneapolis, Minnesota

Annie Wong-Beringer, PharmD, FIDSA
Professor of Pharmacy
School of Pharmacy
University of Southern California
Los Angeles, California

Dinesh Yogaratnam, PharmD, BCPS, BCCCP
Assistant Professor of Pharmacy Practice
School of Pharmacy–Worcester/Manchester
MCPHS University
Worcester, Massachusetts

Kathy Zaiken, PharmD
Professor of Pharmacy Practice
School of Pharmacy–Boston
MCPHS University
Boston, Massachusetts

Caroline S. Zeind, PharmD
Associate Provost for Academic and International Affairs
Chief Academic Officer

Worcester, Massachusetts and Manchester, New Hampshire, Campuses
Professor of Pharmacy Practice
MCPHS University
Boston, Massachusetts

Sara Zhou, PharmD
Certified Poison Information Specialist
Adjunct Assistant Professor
Regional Center for Poison Control Serving Massachusetts and Rhode Island
Boston Children’s Hospital and MCPHS University
Boston, Massachusetts

Kristin M. Zimmerman, PharmD, CGP, BCACP
Associate Professor
Department of Pharmacotherapy & Outcomes Science
Virginia Commonwealth University
Richmond, Virginia

Brief Table of Contents

SECTION 1: GENERAL PRINCIPLES

Section Editors: William W. McCloskey and Maria D. Kostka-Rokosz

1 Medication Therapy Management and Assessment of Therapy
Matthew R. Machado, Amee D. Mistry, and Joseph W. Ferullo

2 Interpretation of Clinical Laboratory Tests
Erika Felix-Getzik, Yulia A. Murray, and Stefanie C. Nigro

3 Drug Interactions
Michelle L. Ceresia, Caroline S. Zeind, John Fanikos, and Michael G. Carvalho

4 Pharmacogenomics and Personalized Medicine
Shannon F. Manzi, Laura Chadwick, and Jonathan D. Picker

5 Managing Drug Overdoses and Poisonings
Iris Sheinhait and Sara Zhou

6 End-of-Life Care
Victoria F. Ferraresi

7 Interprofessional Education and Practice
William W. McCloskey, Edith Claros, Carol Eliadi, and Beth Buyea

SECTION 2: CARDIAC AND VASCULAR DISORDERS

Section Editors: Jean M. Nappi and Judy W. Cheng

8 Dyslipidemias, Atherosclerosis, and Coronary Heart Disease
Barbara S. Wiggins and Pamela B. Morris

9 Essential Hypertension
Judy W. Cheng

10 Peripheral Vascular Disorders
Snehal H. Bhatt and Mary G. Amato

11 Thrombosis
Nancy L. Shapiro and Erika L. Hellenbart

12 Chronic Stable Angina
Angela M. Thompson and Toby C. Trujillo

13 Acute Coronary Syndrome
Brianne L. Dunn and Robert L. Page, II

14 Heart Failure
Harleen Singh and Joel C. Marrs

15 Cardiac Arrhythmias
C. Michael White, Jessica C. Song, and James S. Kalus

16 Hypertensive Crises
Kristin Watson, Brian Watson, and Sandeep Devabhakthuni

17 Shock
Jason S. Haney

SECTION 3: PULMONARY DISORDERS

Section Editors: Timothy R. Hudd and Kathy Zaiken

18 Asthma
Timothy H. Self, Cary R. Chrisman, and Christopher K. Finch

19 Chronic Obstructive Pulmonary Disease
Timothy R. Hudd and Kathy Zaiken

20 Acute and Chronic Rhinitis
Suzanne G. Bollmeier and Dennis M. Williams

21 Cystic Fibrosis
Paul M. Beringer and Michelle Condren

SECTION 4: GASTROINTESTINAL DISORDERS

Section Editor: Carrie A. Sincak

22 Nausea and Vomiting
Lisa M. DiGrazia and Joseph Todd Carter

23 Upper Gastrointestinal Disorders
Elaine J. Law and Jeffrey J. Fong

24 Lower Gastrointestinal Disorders
Toyin Tofade, Benjamin Laliberte, and Charmaine Rochester-Eyeguokan

25 Complications of End-Stage Liver Disease
Yasar O. Tasnif and Mary F. Hebert

SECTION 5: RENAL DISORDERS

Section Editor: Myrna Y. Munar

26 Acid–Base Disorders
Luis S. Gonzalez, III

27 Fluid and Electrolyte Disorders
Alan H. Lau and Priscilla P. How

28 Chronic Kidney Disease
Darius L. Mason

29 Acute Kidney Injury
Susan A. Krikorian and Oussayma Moukhachen

30 Renal Dialysis
Myrna Y. Munar

31 Dosing of Drugs in Renal Failure
David J. Quan

SECTION 6: IMMUNOLOGIC DISORDERS

Section Editor: Steven Gabardi

32 Drug Hypersensitivity Reactions
Greene Shepherd and Justinne Guyton

33 Systemic Lupus Erythematosus
Jerika T. Lam, Ann M. Lynch, and Mary A. Gutierrez

34 Kidney and Liver Transplantation
David J. Taber and Robert E. Dupuis

SECTION 7: NUTRITION ISSUES

Section Editors: R. Rebecca Couris and Susan L. Mayhew

35 Basics of Nutrition and Patient Assessment
Jeff F. Binkley

36 Obesity
Dhiren K. Patel and Kaelen C. Dunican

37 Adult Enteral Nutrition
Carol J. Rollins and Jennifer H. Baggs

38 Adult Parenteral Nutrition
Susan L. Mayhew and Richard S. Nicholas

SECTION 8: DERMATOLOGIC DISORDERS

Section Editor: Timothy J. Ives

39 Dermatotherapy and Drug-Induced Skin Disorders
Richard N. Herrier and Daniel R. Malcom

40 Acne
Jamie J. Cavanaugh and Kelly A. Mullican

41 Psoriasis
Jill A. Morgan, Rachel C. Long, and Timothy J. Ives

42 Photosensitivity, Photoaging, and Burn Injuries
Katherine G. Moore, Molly E. Howard, and Timothy J. Ives

SECTION 9: RHEUMATIC AND MUSCULOSKELETAL DISEASES

Section Editor: Kamala M. Nola

43 Osteoarthritis
Dominick P. Trombetta and Christopher M. Herndon

44 Rheumatoid Arthritis
Steven W. Chen, Rory E. Kim, and Candace Tan

45 Gout and Hyperuricemia
Kimberly Ference and KarenBeth H. Bohan

46 Connective Tissue Disorders
Julie L. Olenak and Jonathan D. Ference

SECTION 10: WOMEN'S HEALTH

Section Editor: Trisha LaPointe

47 Contraception
Shareen Y. El-Ibiary

48 Infertility
Erin C. Raney

49 Obstetric Drug Therapy
Trisha LaPointe

50 Disorders Related to the Menstrual Cycle
Laura M. Borgelt and Karen M. Gunning

51 The Transition Through Menopause
Louise Parent-Stevens and Trisha LaPointe

SECTION 11: ENDOCRINE DISORDERS

Section Editor: Jennifer D. Goldman

52 Thyroid Disorders
Eric F. Schneider and Betty J. Dong

53 Diabetes Mellitus
Jennifer D. Goldman, Dhiren K. Patel, and David Schnee

SECTION 12: EYE DISORDERS

Section Editor: Susan Jacobson

54 Eye Disorders
Steven R. Abel and Suellyn J. Sorensen

SECTION 13: NEUROLOGIC DISORDERS

Section Editors: Michele Matthews and Timothy E. Welty

55 Pain and Its Management
Lee A. Kral and Virginia L. Ghafoor

56 Care of the Critically Ill Adult
Matthew Hafermann, Philip Grgurich, and John Marshall

57 Multiple Sclerosis
Melody Ryan

58 Headache
Steven J. Crosby

59 Parkinson’s Disease and Other Movement Disorders
Kristin M. Zimmerman and Natalie Whitmire

60 Seizure Disorders
James W. McAuley and Brian K. Alldredge

61 Ischemic and Hemorrhagic Stroke
Oussayma Moukhachen and Philip Grgurich

SECTION 14: INFECTIOUS DISEASES

Section Editors: Dorothea C. Rudorf, G. Christopher Wood, and Caroline S. Zeind

62 Principles of Infectious Diseases
B. Joseph Guglielmo

63 Antimicrobial Prophylaxis for Surgical Procedures
Daniel J. G. Thirion

64 Vaccinations
Molly G. Minze and Katherine Dillinger Ellis

65 Central Nervous System Infections
Gregory A. Eschenauer, Deanna Buehrle, and Brian A. Potoski

66 Endocarditis
Michelle L. Chan and Annie Wong-Beringer

67 Respiratory Tract Infections
Jason Cross, Evan Horton, and Dinesh Yogaratnam

68 Tuberculosis
Michael B. Kays

69 Infectious Diarrhea
Gail S. Itokazu and David T. Bearden

70 Intra-Abdominal Infections
Sheila K. Wang and Carrie A. Sincak

71 Urinary Tract Infections
Douglas N. Fish

72 Sexually Transmitted Diseases
Jeffery A. Goad, Karl M. Hess, and Albert T. Bach

73 Osteomyelitis and Septic Arthritis
Jacqueline L. Olin, Linda M. Spooner, and Karyn M. Sullivan

74 Skin and Soft Tissue Infections
Cheryl R. Durand and Kristine C. Willett

75 Prevention and Treatment of Infections in Neutropenic Cancer Patients
Richard H. Drew

76 Pharmacotherapy of Human Immunodeficiency Virus Infection
Jessica L. Adams and Mackenzie L. Cottrell

77 Opportunistic Infections in HIV-Infected Patients
Emily L. Heil and Amanda H. Corbett

78 Fungal Infections
John D. Cleary and Russell E. Lewis

79 Viral Infections
Milap C. Nahata, Neeta Bahal O’Mara, and Sandra Benavides

80 Viral Hepatitis
Jerika T. Lam and Curtis D. Holt

81 Parasitic Infections
Sheila Seed, Larry Goodyer, and Caroline S. Zeind

82 Tick-Borne Diseases
Caroline S. Zeind, Michelle L. Ceresia, and Lin H. Chen

SECTION 15: PSYCHIATRIC DISORDERS AND SUBSTANCE ABUSE

Section Editors: Michael C. Angelini and Michael G. Carvalho

83 Anxiety Disorders
Jolene R. Bostwick and Kristen N. Gardner

84 Sleep Disorders
Devon A. Sherwood and Anna K. Morin

85 Schizophrenia
Richard J. Silvia, Robert L. Dufresne, and Justin C. Ellison

86 Depressive Disorders
Michael C. Angelini

87 Bipolar Disorders
Megan J. Ehret and Charles F. Caley

88 Developmental Disorders
Lee A. Robinson and Kimberly Lenz

89 Attention Deficit Hyperactivity Disorder in Children, Adolescents, and Adults
Michael C. Angelini and Joel Goldstein

90 Substance Use Disorders
Michael C. Angelini

91 Tobacco Use and Dependence
Andrea S. Franks and Sarah E. McBane

SECTION 16: HEMATOLOGY AND ONCOLOGY

Section Editor: Christy S. Harris

92 Anemias
Cindy L. O'Bryant, Ashley E. Glode, and Lisa A. Thompson

93 Neoplastic Disorders and Their Treatment: General Principles
Jaime E. Anderson, Andrea S. Dickens, and Katherine Tipton Patel

94 Adverse Effects of Chemotherapy and Targeted Agents
Amy Hatfield Seung and Emily Mackler

95 Pediatric Malignancies
David W. Henry and Nicole A. Kaiser

96 Adult Hematologic Malignancies
Lynn Weber, Jacob K. Kettle, Andy Kurtzweil, Casey B. Williams, Rachel Elsey, and Katie A. Won

97 Breast Cancer
Kellie Jones Weddle

98 Lung Cancer
Sara K. Butler

99 Colorectal Cancer
Marlo Blazer

100 Prostate Cancer
Marina D. Kaymakcalan and Christy S. Harris

101 Hematopoietic Cell Transplantation
Valerie Relias

SECTION 17: PEDIATRICS

Section Editor: Marcia L. Buck

102 Pediatric Pharmacotherapy
Marcia L. Buck

103 Pediatric Fluid, Electrolytes, and Nutrition
Michael F. Chicella and Jennifer W. Chow

104 Common Pediatric Illnesses
Chephra McKee, Brooke Gildon, and Bethany Ibach

105 Neonatal Therapy
Donna M. Kraus, Jennifer T. Pham, and Kirsten H. Ohler

106 Care of the Critically Ill Child
Elizabeth Anne Farrington and Marcia L. Buck

SECTION 18: GERIATRIC THERAPY

Section Editor: Judith L. Beizer

107 Geriatric Drug Use
Suzanne Dinsmore, Mary-Kathleen Grams, and Kristin Zimmerman

108 Geriatric Neurocognitive Disorders
Nicole J. Brandt and Bradley R. Williams

109 Geriatric Urologic Disorders
Tran H. Tran

110 Osteoporosis
R. Rebecca Couris, Suzanne Dinsmore, and Mary-Kathleen Grams

Drug Index
Subject Index

Detailed Table of Contents

SECTION 1: General Principles

Section Editors: William W. McCloskey and Maria D. Kostka-Rokosz

1 Medication Therapy Management and Assessment of Therapy
Matthew R. Machado, Amee D. Mistry, and Joseph W. Ferullo

Sources of Patient Information
Effective Communication and the Patient Interview
Obtaining a Patient History
Approach to and Assessment of Patient Therapy
Medication Therapy Management Services in the Community Pharmacy or Ambulatory Setting
Medication Therapy Management in the Acute Care Setting
Medication Therapy Management and Pharmacogenomics
Conclusion
Acknowledgment
Key References and Websites

2 Interpretation of Clinical Laboratory Tests
Erika Felix-Getzik, Yulia A. Murray, and Stefanie C. Nigro

General Principles
Fluids and Electrolytes
Multichemistry Panels
Proteins
Cardiac Markers
Liver Function Tests
Miscellaneous Tests
Hematology
Urinalysis
Therapeutic Drug Monitoring
Patient-Directed Monitoring and Testing
Key References and Websites

3 Drug Interactions
Michelle L. Ceresia, Caroline S. Zeind, John Fanikos, and Michael G. Carvalho

Definition
Risk Factors for Drug Interactions
Mechanisms of Drug Interactions
Management of Drug Interactions
Resources and Evidence for Clinical Decision Support
Conclusion
Key References and Websites

4 Pharmacogenomics and Personalized Medicine
Shannon F. Manzi, Laura Chadwick, and Jonathan D. Picker

Pharmacokinetic Implications
Pharmacodynamic Implications
Toxicity Implications
Drug Target Implications
Nonmetabolism Implications
The Peculiarities of Cyp2d6
Developmental Impact and Pharmacogenomics
Family Implications of Pharmacogenetics
Making the Case for Pharmacogenetics
Conclusion
Key References and Websites

5 Managing Drug Overdoses and Poisonings
Iris Sheinhait and Sara Zhou

General Management
Assessment of Salicylate Ingestion
Assessment of Iron Ingestion
Assessment of Central Nervous System Depressant Versus Antidepressant Ingestion
Assessment of Acetaminophen Ingestion
Conclusion
Key References and Websites

6 End-of-Life Care
Victoria F. Ferraresi

Hospice and Palliative Care
Symptom Management

Medication Therapy Management and Assessment of Therapy

Matthew R. Machado, Amee D. Mistry, and Joseph W. Ferullo

CORE PRINCIPLES		CHAPTER CASES
1	Medication Therapy Management Services (MTMS) are a service or group of services that optimize therapeutic outcomes for individual patients.	**Case 1-5 (Questions 1–4)**
2	A successful MTMS encounter includes medication reconciliation and a comprehensive medication history.	**Case 1-1 (Questions 1–3)**
3	Sources of patient information for MTMS include the patient, the electronic health record, the paper chart, and the pharmacy information system.	**Case 1-5 (Questions 1, 5), Table 1-1**
4	A careful and complete patient interview should include medical, medication, and social histories, and it must be provided in a culturally sensitive manner.	**Case 1-1 (Questions 1–3), Table 1-2, Online Content**
5	A successful MTMS encounter must be well documented following the Problem Oriented Medical Record (POMR). Documentation involves collecting subjective and objective data to identify the primary problem.	**Case 1-5 (Question 1), Table 1-4** **Case 1-2 (Question 1),** **Case 1-3 (Question 1),** **Case 1-4 (Question 1)**
6	The clinician must assess the drug therapy or disease-specific problem and create a treatment plan.	**Case 1-5 (Questions 1, 2)**
7	The final step in documenting the MTMS encounter is developing the medication action plan and processing any billing requirements.	**Case 1-5 (Questions 1, 2, 4)**
8	Accurate and complete communication of the MTMS encounter to the patient’s health care team is vital.	**Case 1-5 (Question 3)**

This chapter discusses medication therapy management services (MTMS) with a focus on the assessment of drug therapy. The illustrations in this chapter primarily focus on the pharmacist; however, the principles used to assess patient response to drug therapy are of value to all health care providers.

As defined by the American Pharmacists Association, medication therapy management (MTM) is a term used to describe a broad range of health care services provided by pharmacists, the medication experts on the health care team. A consensus definition created by 11 pharmacy associations, adopted by the pharmacy profession in 2004, defines MTM as a service or group of services that optimize therapeutic outcomes for individual patients.[1] Pharmacists provide MTM to help patients get the best benefits from their medications by actively managing drug therapy and by identifying, preventing, and resolving medication-related problems.

MTM has a direct relationship to pharmaceutical care. Pharmaceutical care has been described as the responsible provision of drug therapy to achieve definite outcomes that are intended to improve a patient's quality of life.[2,3] In fact, MTM has been described as a service provided in the practice of pharmaceutical care.[4] However, unlike pharmaceutical care, MTM is recognized by payers, has current procedural terminology (CPT) codes specifically for pharmacists, and has several clearly defined interventions. Therefore, MTMS will be the term used to describe the activity of MTM in various patient populations.

With the passage of the Patient Protection and Affordable Care Act and the Health Care and Education Reconciliation Act of 2010, pharmacists have tremendous opportunities in the implementation of health care reform.[5,6] One of the hallmarks of this law is delivery system reform. As health care delivery systems change, pharmacists have an opportunity to improve overall quality of care, to become involved in coordinated health care approaches such as medical home teams and accountable care organizations, and to collaborate to improve care for high-risk patients and those with chronic conditions in primary-care settings. In the United States, there are an estimated 133 million people that have at least one chronic medical condition.[7] In 2010, 86% of all health care spending was for people with one or more chronic health condition(s).[8] Pharmacists will have additional opportunities as hospitals will have financial incentives to improve quality, reduce costs, and decrease hospital-acquired conditions.[5,6]

Both patient self-care and medication reconciliation are critical aspects of any MTMS encounter regardless of the setting (i.e., inpatient, community, ambulatory, or institutional). Patient self-care requires the patient to take responsibility for the illness; however, the help of a professional to structure healthy self-care is important. For example, patients with diabetes who monitor their blood glucose levels regularly and adjust their diet according to the guidelines published from the American Diabetes Association (ADA) would be practicing self-care. Self-care is often the work that the patient performs between visits with the provider. The patient should be involved in his or her own care to ensure the best outcomes.

Medication reconciliation is the comprehensive evaluation of a patient's medication regimen any time there is a change in therapy in an effort to avoid medication errors such as omissions, duplications, dosing errors, or drug interactions, as well as to observe compliance and adherence patterns. This process should include a comparison of the existing and previous medication regimens and should occur at every transition of care in which new medications are ordered, existing orders are rewritten or adjusted, or when the patient has added nonprescription medications to his or her self-care.[9] Although not a new concept to the profession of pharmacy, there has been heightened awareness and intensified effort in this area of practice as a result of the Joint Commission. In 2005, the Joint Commission announced its National Patient Safety Goal (NPSG) 8A and 8B to accurately and completely reconcile medications across the continuum of care. This goal requires institutions to develop and test processes for medication reconciliation in ambulatory and acute care settings.[10] In 2015, the Joint Commission's NPSG 3 has continued its focus on improving the safe use of medications, in particular by maintaining and communicating accurate patient medical information.[11]

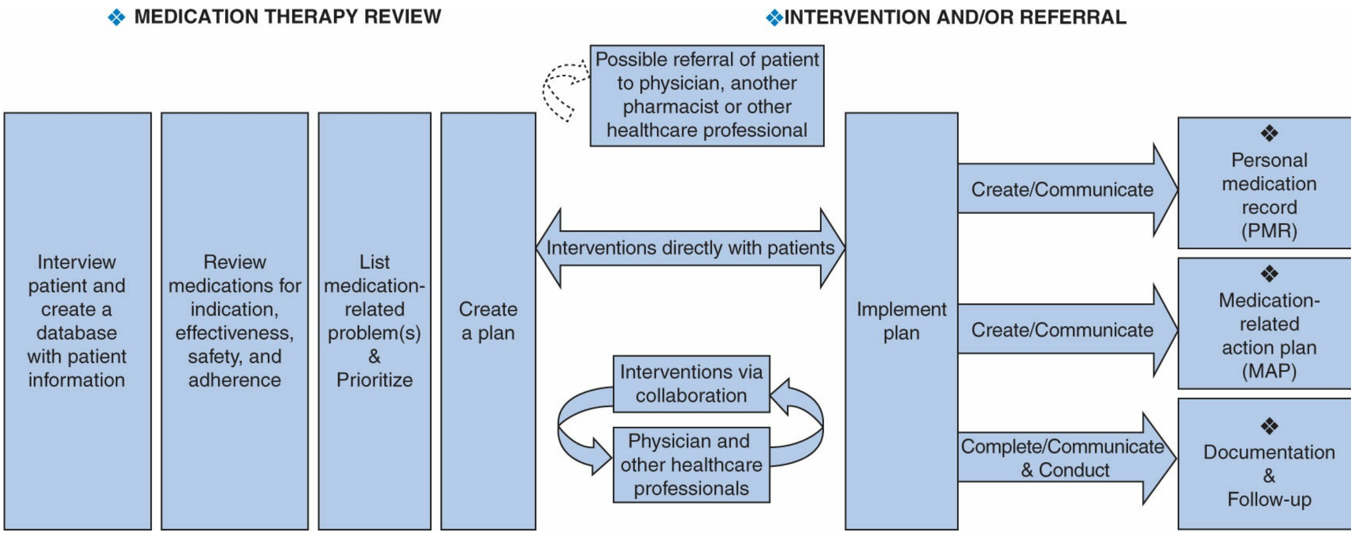
The Centers for Medicare & Medicaid Services (CMS), the largest purchaser of health insurance in the United States, is directly connecting reimbursement for Medicare services to patient outcomes. CMS developed star ratings as a means to move away from the Pay-for-Service Model of healthcare and move toward a new quality based or Pay-for-Performance Model. CMS annually rates Medicare health plans on a scale of 1 to 5 stars, with 5 stars representing the highest quality. The overall scores are based on more than 50 care and service quality measures across five categories, including staying healthy, managing chronic conditions, member satisfaction, customer service, and pharmacy services. Specific to pharmacy services, CMS assesses Medicare prescription drug plans (MA-PD's or PDPs) using its rating scale, focusing on five quality measures. Two of those quality measures assess medication safety, while the other three evaluate adherence. The quality measures that focus on safety look at decreasing the amount of high-risk medications (HRMs) in patients 65 and older and whether diabetic patients who also have hypertension are taking an ACE Inhibitor, Angiotensin Receptor Blocker (ARB), or Direct Renin Inhibitor. (To view complete list of HRM's visit website: https://www.cms.gov/Medicare/Medicare-Fee-for-Service-Payment/PhysicianFeedbackProgram/Downloads/Elderly-High-Risk-Medications-DAE.pdf) CMS will monitor adherence through three separate measures that focus on evaluating the level of adherence of patients who are on medications for diabetes, hypertension, or hypercholesterolemia, specifically statins.[12] In August 2013, CMS released a study demonstrating that in 2010 Medicare Part D MTM programs improved therapy outcomes, most notably adherence, on patients who had congestive heart failure (HF), chronic obstructive pulmonary disease, and diabetes compared to those who did not receive such services.[13]

It is important for pharmacists to realize that MTMS are integral to improving health outcomes and are continuing to gain acceptance from payers, in both the private and public sectors. The opportunity for pharmacists to continue to expand their role, while offering high level care, along with the potential for improvement in pharmacy compensation is in line with the CMS star ratings.

The general approach to an MTMS patient encounter in various clinical settings will be discussed in the next sections. Figure 1-1 provides a visual representation of a systematic process for a comprehensive and effective approach for delivering MTMS.

SOURCES OF PATIENT INFORMATION

Successful patient assessment and monitoring requires gathering and organizing relevant information.[3,14] The patient (or family member or representative) is always the primary source of information. The provider asks the patient a series of questions to obtain subjective information that is helpful in making a diagnosis or evaluating ongoing therapy. Likewise, providers without direct access to patient data must also obtain subjective data or measure objective physical data to guide recommendations for therapy and to monitor previously prescribed therapy.



❖ MEDICATION THERAPY REVIEW
❖ INTERVENTION AND/OR REFERRAL
Interview patient and create a database with patient information
Review medications for indication, effectiveness, safety, and adherence
List medication-related problem(s) & Prioritize
Create a plan
Possible referral of patient to physician, another pharmacist or other healthcare professional
Interventions directly with patients
Interventions via collaboration
Physician and other healthcare professionals
Implement plan
Create/Communicate
Create/Communicate
Complete/Communicate & Conduct
❖ Personal medication record (PMR)
❖ Medication-related action plan (MAP)
❖ Documentation & Follow-up

Figure 1-1 General approach to an MTMS patient encounter. (Reproduced from the American Pharmacists Association [APhA], with permission.)

Data-Rich and Data Poor Environments

In a “data-rich environment,” such as a hospital, long-term facility, or outpatient medical clinic, a wealth of information is available to practitioners from the medical record, pharmacy profile, and medication administration record (MAR). In these settings, physicians, nurses, other health care providers, and patients are readily available. This facilitates timely, effective communication among providers involved in the drug therapy decision-making process. Objective data (e.g., diagnosis, physical examination, laboratory and other test results, vital signs, weight, medications, medication allergies, intravenous flow rates, and fluid balance) are readily available. The patient record provides information that is needed to identify and assess medical problems, which is necessary to design patient-specific care plans and document MTMS. In some settings, patient insurance information is important to help understand the formulary choices and access to medications.

In a "data-poor environment," such as a community pharmacy, clinicians are often required to make assessments with limited information. Although the information may be limited to (a) the medication profile, (b) patient demographic data, (c) medication allergy history, and (d) the patient's insurance coverage, it is still valuable.

The information in Table 1-1 is an illustrative summary of sources of patient information.

Table 1-1

Sources of Patient Information

Data-Rich Environment	Data-Poor Environment

Paper Charts
▪ Decreasing use across the practice continuum
▪ Limitations
  ▪ Not consistent from site to site
  ▪ Difficult to access, if more than one user
  ▪ Delays in data entry
Electronic Health Record (EHR)
▪ Electronic version of a paper chart
▪ Differs across practice settings
▪ One of the most complete sources of reliable information
▪ Can interface with other software systems in the pharmacy, laboratories, etc.
▪ Data shared between systems in real time
	Pharmacy Information Systems (PIS)—Outpatient and Inpatient
	▪ Mainly focus on pharmacy billing, inventory management, production of medication labels
	▪ Limited documentation of clinical pharmacy

Pharmacy information systems (PIS) are generally considered data poor. Early PIS were established for pharmacy billing and inventory management. These initial systems provided fill lists, generated patient profiles, and produced medication labels, which were valuable to institutional pharmacies as the profession moved toward a unit dose medication distribution system. More modern functionalities allow for some limited documentation of clinical pharmacy activities, but still PIS is considered to be data poor.

An initiative by the US Department of Health and Human Services, called the EHR Incentive Program, exemplifies the importance of the integration of PIS with other computerized systems.[15] This initiative, the “Meaningful Use of an EHR,” allows Medicare and Medicaid to provide incentive payments to providers and hospitals for the “meaningful use” of certified health information technology products. Eligibility for these incentive payments involves transitioning PIS to a more data-rich clinical information system (CIS), which includes direct computerized physician order entry, clinical decision support, an EHR, an electronic medication administration record (eMAR), and integration of various information systems, such as pharmacy and laboratory services. Additional functionality incorporates the use of bar code technology, which allows the ability to track and promote quality assurance during the medication administration process. Information generated by the CIS is electronically transmitted to the pharmacy in real time, eliminating lost, illegible, or incomplete medication orders.

In a data-poor environment, the clinician must be a proactive interviewer and may become an investigator. The investigative approach is direct and requires strong problem-solving abilities and active listening skills. Questions should be formulated to obtain information such as the medication history, actual medication use, patient perception of care, use of over-the-counter (OTC) and natural or herbal products, and health beliefs (cultural or otherwise). This approach can help to verify and ensure the accuracy of other data sources. Clinicians should be mindful that not all patients are reliable historians, and some are poor sources of information. Even when the patient is a poor historian, the interview provides critical information (e.g., indicator of poor adherence, need for a caregiver or interpreter) that cannot be obtained from other sources.

EFFECTIVE COMMUNICATION AND THE PATIENT INTERVIEW

The ability to use effective communication principles and history-taking skills is crucial to a successful patient interaction.[3,14] The importance of interviewing the patient, how to set the stage for the interview, general interview rules, and the essential information to be obtained from the interview are outlined in Table 1-2. Information obtained from the patient is critical for assessment and planning in MTM.

Motivational Interviewing (MI) is another useful method created by Miller and Rollnick that can be utilized during patient counseling to improve patient adherence to therapy. It is an empathetic and collaborative style of counseling based on five key principles: expressing empathy, developing discrepancy, adapting to resistance, avoiding arguments, and supporting self-efficacy, as seen in Table 1-3. The basis of MI is aimed to improve a patient’s ambivalence to drug therapy through behavioral changes. It should be noted that motivational interviewing does not require a long-standing pharmacist–patient relationship to be effective, because individual sessions have been shown to be helpful.[16,17]

Table 1-2

Interviewing the Patient

Importance of Interviewing the Patient

Establishes professional relationship with the patient to:

- Obtain subjective data on medical problems
- Obtain patient-specific information on drug efficacy and toxicity
- Assess the patient's knowledge about, attitudes toward, and pattern of medication use
- Formulate a problem list
- Formulate plans for medication teaching and pharmaceutical care

How to Set the Stage for the Interview

- Have the patient complete a written health and medication questionnaire, if available
- Make the setting as private as possible
- Maintain eye contact
- Encourage the patient to be descriptive
- Clarify by restatement or patient demonstration (e.g., of a technique)

General Interview Rules

- Read the chart or patient profile first
- Ask for the patient's permission to conduct an interview or make an appointment to do so
- Begin with open-ended questions
- Move to close-ended questions
- Document interaction

Information to be Obtained

- History of allergies
- History of adverse drug reactions
- Weight and height
- Drugs: dose, route, frequency, and reason for use
- Perceived efficacy of each drug
- Perceived side effects
- Adherence to prescribed drug regimen
- Nonprescription medication use (including complementary and alternative medications)
- Possibility of pregnancy in women of childbearing age
- Family or other support systems

Table 1-3

Principles of Motivational Interviewing

Expressing empathy	Convey to your patient that you understand their condition. This will allow the patient to be more open minded.
Develop discrepancy	Point out to the patient that there is a difference between current behavior and being able to reach their goals.
Adapt to resistance	Use different approaches to encourage the patient to channel their resistance into positive change.
Avoid arguments	Do not argue with your patient or force them to view things as you do.
Support self-efficacy	Assist the patient with believing that their own decisions will make a difference to behavioral change. Instead of telling the patient what to do, empower them to figure out what will be effective.

Enhancing motivation for change in substance abuse treatment. Rockville, MD: substance abuse and mental health services administration (US); 1999. (Treatment Improvement Protocol (TIP) Series, No. 35.) Chapter 3—Motivational Interviewing as a Counseling Style. Available from: **http://www.ncbi.nlm.nih.gov/books/NBK64964/**

OBTAINING A PATIENT HISTORY

Those who provide MTMS should develop standardized forms to record patient information obtained from the patient interview. Standardization facilitates quick retrieval of information, minimizes the inadvertent omission of data, and enhances the ability of other practitioners to use shared records.[3,14]

The patient interview and record can be divided into sections with subjective and objective data as well as an assessment and plan (including expected outcomes). Components of subjective and objective data are the medical history, medication history, and social history. In some situations, histories can be supplemented by the generation of flowchart diagrams to monitor changes in specific variables with time. These charts and documentation systems may be incorporated into the EHR, PIS, or a similar electronic platform.

Medical History

A medical history is essential to the provision of MTMS. It can be as extensive as the medical records that are maintained in an institution or physician's office, or it can be a simple patient profile that is maintained in a community pharmacy. The purpose of the medical history is to identify significant past medical conditions or procedures; identify, characterize, and assess current acute and chronic medical conditions and symptoms; and gather all relevant health information that could influence drug selection or dosing (e.g., function of major organs such as the gastrointestinal tract, liver, and kidney; height and weight, including recent changes in either; age and sex; pregnancy and lactation status; and special nutritional needs). Not all interviews require the interviewer to ask for this much general information; however, in a data-poor environment, more information is required directly from the patient. A more focused interview may be appropriate in settings in which the information required is available electronically or is specific to a single disease state.

CASE 1-1

QUESTION 1: P.J., a 45-year-old woman of normal height and weight, states that she has diabetes. What questions might the practitioner ask P.J. to determine whether type 1 or type 2 diabetes should be documented in her medical history?

Patients usually can enumerate their medical problems in a general way, but the practitioner often will have to probe more specifically to refine the diagnosis and assess the severity of the condition. Diabetes mellitus is used to illustrate the types of questions that can be used to gather important health information and assess drug therapy. The following questions should generate information that will help to determine whether P.J. has type 1 or type 2 diabetes.

- How old were you when you were told you had diabetes?
- Do any of your relatives have diabetes? What do you know of their diabetes?
- Do you remember your symptoms? Please describe them to me.
- What medications have you used to treat your diabetes?

When questions such as these are combined with knowledge of the pathophysiology of diabetes, appreciation of the typical presenting signs and symptoms of the disease, and understanding of the drugs generally used to treat both forms of diabetes, meaningful MTM can be provided.

Medication History

In the community pharmacy setting, patients generally present themselves in one of four ways: (a) with a self-diagnosed condition for which nonprescription drug therapy is sought, (b) with a newly diagnosed condition for which a drug has been prescribed, (c) with a chronic condition that requires a refill of a previously prescribed drug or the initiation of a new drug, or (d) upon referral from their health plan or provider, or self-referral for focused medication therapy review (MTR).

In the first and second situations, the practitioner must confirm the diagnosis by using disease-specific questions as illustrated in Question 1. In the third situation, the practitioner uses the same type of questioning as in the first two situations; however, this time the practitioner needs to evaluate whether the desired therapeutic outcomes have been achieved. The practitioner must evaluate the information gleaned during follow-up visits in the context of the history and incorporate it into his or her assessment and medication action plan (MAP). In the fourth situation, in which patients require a focused MTR, the medication and medical history information are equally important. Without the medical history, it is not possible to evaluate whether the drug therapy is appropriate, and without an accurate medication history, it is not possible to determine whether the patient has reached the desired goals of therapy for her condition.

The goal of the medication history is to obtain and assess the following information: the specific prescription and nonprescription drugs that the patient is taking (such as OTC medications, botanicals, dietary supplements, recreational drugs, alcohol, tobacco, and home remedies); the intended purpose or indications for each of these medications; how it is taken (e.g., route, ingestion in relation to meals), how much, and how often these medications are used; how long these agents have been taken or used (start and stop dates); whether the patient believes that any of these agents are providing therapeutic benefit; whether the patient is experiencing or has experienced any adverse effects that could be caused by each of these agents (idiosyncratic reactions, toxic effects, adverse effects); whether the patient has stopped taking any of the medications for any reason; and allergic reactions or history of hypersensitivity or other severe reactions to drugs. This information should be as specific as possible, including a description of the reaction, the treatment, and the date of its occurrence.

A successful medication reconciliation process consists of a standardized systematic approach, with the initial step in this process involving the collection of the best medication history possible from every patient that enters any point in the health care system. Although pharmacists are uniquely qualified and have demonstrated increased accuracy in acquiring the medication history,[18] medication reconciliation requires a multidisciplinary effort in which all available resources are integrated into each step of the process when appropriate.[19] Shared accountability by using key members of the health care team such as nurses, pharmacy technicians, pharmacists, and prescribers is essential in this process. Once an accurate medication history is obtained, this information is used to ensure that as the patient moves through the health care system, any deviation from prescribed regimen is deliberate and based on acute changes in the patient’s condition. If an observed discrepancy is the result of an intended therapeutic decision by the prescribing clinician, appropriate documentation with either the reason for or intention to change, hold, or discontinue the medication should be completed in a manner that is clear to all members of the health care team. Unintentional variances in the medication lists should be considered as potential medication errors pending clarification from the prescribing clinician.

Medication errors most commonly occur during transitions of care. It is essential to conduct medication reconciliation when a patient is admitted to or discharged from a health care facility.[20,21] A crucial final step in the reconciliation process, and a vital piece of MTMS, occurs at discharge to avoid therapeutic duplication, drug interactions, and omissions of medications that may have been discontinued or placed on hold during hospitalization. On departure from a health care facility, a complete list of the patient's medications must be communicated to the patient and the next provider of service regardless of the setting. This process allows for informed prescribing decisions and creates a safer environment for patients by improving the accuracy of medication administration throughout the continuum of care.

Perhaps the most important aspect of the medication history is to ensure that no assumptions related to medication use go unverified with the patient. The provider should ask questions related to how the current medication therapy is actually taken by the patient. The interviewer should then compare the use of medications as defined by the patient to the prescription information on the prescription bottle or in the PIS/EHR. This information may identify discrepancies or misunderstandings between the prescriber and the patient. The patient may not have adequate health literacy, and the interpretation of the medication instructions printed on the bottle or described by a health professional may not be understandable to a patient. The review of the medication history is an ideal time to identify and clarify such misunderstandings.

CASE 1-1, QUESTION 2: P.J. has indicated that she is injecting insulin to treat her diabetes. What questions might be asked to evaluate P.J.'s use of and response to insulin?

The following types of questions, when asked of P.J., should provide the practitioner with information on P.J.'s understanding about the use of and response to insulin.

DRUG IDENTIFICATION AND USE

- What type of insulin do you use?
- How many units of insulin do you use?
- When do you inject your insulin?
- Where do you inject your insulin?
- Please show me how you usually prepare your insulin for injection. (This allows t patient to demonstrate a skill.)
- What, if anything, keeps you from taking your insulin as prescribed?

ASSESSMENT OF THERAPEUTIC RESPONSE

- How do you know your insulin is working?
- What blood glucose levels are you aiming for?
- What foods or meals do you find affect your blood sugar most?
- How often and when do you test your blood glucose level?
- Do you have any blood glucose readings that you could share with me?
- Please show me how you test your blood glucose.

- What is your understanding of the hemoglobin A_{1c} blood test?
- When was the last time you had this test done?
- What were the results of the last hemoglobin A_{1c} test?

ASSESSMENT OF ADVERSE EFFECTS

- Do you ever experience reactions from low blood glucose?
- What symptoms warn you of such a reaction?
- When do these typically occur during the day?
- How often do they occur?

- What circumstances seem to make them occur more frequently?
- What do you do when you have low blood glucose?
- The patient’s responses to these questions on drug use, therapeutic response, and adverse effects will allow a quick assessment of the patient’s knowledge of insulin and whether she is using it in a way that is likely to result in blood glucose concentrations that are neither too high nor too low. The responses to these questions should also provide the practitioner with insight about the extent to which the patient has been involved in establishing and monitoring therapeutic outcomes. Based on this information, the practitioner can begin to formulate the patient’s therapeutic plan.

Social History

The social history is used to determine the patient’s occupation and lifestyle; important family relationships or other support systems; any particular circumstances (e.g., a disability) or stresses in her life that could influence the MAP; and attitudes, values, and feelings about health, illness, and treatments.

CASE 1-1, QUESTION 3: A patient’s occupation, lifestyle, insurance status, ability to pay, and attitudes often can determine the success or failure of drug therapy. Therefore, P.J.’s prescription drug coverage, nutritional history, her level of activity or exercise in a typical day or week, the family dynamics, and any particular stresses that may affect glucose control need to be documented and assessed. What questions might be asked of P.J. to gain this information?

WORK

- Describe your typical workday and a typical weekend day.

INSURANCE/COST

- What type of prescription drug coverage do you have? How much do you pay for your insulin and diabetic supplies? How often do you go without your insulin or supplies because of cost?

EXERCISE

- Describe your exercise habits. How often, how long, and when during the day do you exercise? Describe how you change your meals or insulin when you exercise.

DIET

- How many times per day do you usually eat? Describe your usual meal times.
- What do you usually eat for each of your main meals and snacks?
- Are you able to eat at the same time each day?
- What do you do if a meal is delayed or missed?
- Who cooks the meals at home? Does this person understand foods to prepare for someone with diabetes?
- How often do you eat meals in a restaurant?
- How do you order meals in a restaurant to maintain a proper diet for your diabete (Note: This is asked to patients who frequently dine in restaurants.)

SUPPORT SYSTEMS

- Who else lives with you? What do they know about diabetes? How do they respor to the fact that you have diabetes? How do they help you with your diabetes management? Does it ever strain your relationship? What are the issues that seem to be most troublesome? (Note: These questions apply equally to the workplace or school setting. Often, the biggest barrier to multiple daily injections is refusal of the patient to inject insulin while at work or school.)

ATTITUDE

- How do you feel about having diabetes?
- What worries or bothers you most about having diabetes? (Note: Participate in the patient's care. This approach is likely to enhance the patient–provider relationship, which should translate into improved care.)

APPROACH TO AND ASSESSMENT OF PATIENT THERAPY

The provider–patient encounter will vary based on the location and type of services provided and access to necessary information. However, the general approach to the patient encounter should follow the problem-oriented medical record (POMR). Organizing information according to medical problems (e.g., diseases) helps to break down a complex situation (e.g., a patient with multiple medical problems requiring multiple drugs) into its individual parts.[1,2] The medical community has long used a POMR or SOAP note to record information in the medical record or chart by using a standardized format (Table 1-4). Each medical problem is identified, listed sequentially, and assigned a number. Subjective data and objective data in support of each problem are delineated, an assessment is made, and a plan of action identified. The first letter of the four key words (subjective, objective, assessment, and plan) serves as the basis for the SOAP acronym.

Table 1-4

Elements of the Problem-Oriented Medical Record

Problem name: Each "problem" is listed separately and given an identifying number. Problems may be a patient complaint (e.g., headache), a laboratory abnormality (e.g., hypokalemia), or a specific disease name if prior diagnosis is known. When monitoring previously described drug therapy, more than one drug-related problem may be considered (e.g., lack of adherence, an adverse drug reaction or drug interaction, or inappropriate dose). Under each problem name, the following information is identified:	
Subjective	Information that explains the reason for the encounter. Information that the patient reports concerning symptoms, previous treatments, medications used, and adverse effects encountered. These are considered nonreproducible data because the information is based on the patient's interpretation and recall of past events.
Objective	Information from physical examination, laboratory test results, diagnostic tests, pill counts, and pharmacy patient profile information. Objective data are measurable and reproducible.
Assessment	A brief but complete description of the problem, including a conclusion or diagnosis that is supported logically by the above subjective and objective data. The assessment should not include a problem or diagnosis that is not defined above.
Plan	A detailed description of recommended or intended further workup (laboratory tests, radiology, consultation), treatment (e.g., continued observation, physiotherapy, diet, medications, surgery), patient education (self-care, goals of therapy, medication use, and monitoring), monitoring, and follow-up relative to the above assessment.

Sometimes referred to as the SOAP (subjective, objective, assessment, plan) note.

The POMR is a general approach and helps to focus on the encounter, which provides a structure for the documentation of the services provided. The following section will describe the POMR and SOAP note in more detail.

Problem List

Problems are listed in order of importance and are supported by the subjective and objective evidence gathered during the patient encounter. Each problem in the list can then be given an identifying number. All subsequent references to a specific problem can be identified or referenced by that number (e.g., "problem 1" or simply "1"). These are generally thought of in terms of a diagnosed disease, but they also may be a symptom complex that is being evaluated, a preventive measure (e.g., immunization, contraception), or a cognitive problem (e.g., lack of adherence). Any condition that requires a unique management plan should be identified as a problem to serve as a reminder to the practitioner that treatment is needed for that problem. Different settings and activities or clinical services will determine the priority of the problems identified.

Medical problems can be drug related, including prescribing errors, dosing errors, adverse drug effects, adherence issues, and the need for medication counseling. Drug-related problems may be definite (i.e., there is no question that the problem exists) or possible (i.e., further investigation is required to determine if the problem really exists). The most commonly encountered types of drug-related problems are listed in Table 1-5.[3,14]

The distinction between medical problems and drug-related problems sometimes is unclear, and overlap can exist. For example, a medical problem (i.e., a disease, syndrome, symptom, or health condition) can be prevented, cured, alleviated, or exacerbated by medications. When assessing drug therapy, several situations could exist: treatment is appropriate and therapeutic outcomes have been achieved; drugs that have been selected are ineffective or therapeutic outcomes are partially achieved; dosages are subtherapeutic or medication is taken improperly; an inappropriate drug for the medical condition being treated has been prescribed or is being used; or the condition is not being treated.

Likewise, a drug-related problem can cause or aggravate a medical problem. Such drug-related problems could include hypersensitivity reactions; idiosyncratic reactions; toxic reactions secondary to excessive doses; adverse reactions (e.g., insulin-induced hypoglycemia or weight gain); drug–drug, drug–disease, drug–laboratory test, and drug–lifestyle interactions; or polypharmacy, which may increase the risk of adverse drug events.[22]

Table 1-5

Drug-Related Problems

Drug Needed
Drug indicated but not prescribed; a medical problem has been diagnosed, but there is no indication that treatment has been initiated (maybe it is not needed)
Correct drug prescribed but not taken (lack of adherence)
Wrong or Inappropriate Drug
No apparent medical problem justifying the use of the drug
Drug not indicated for the medical problem for which it has been prescribed
Medical problem no longer exists
Duplication of other therapy
Less expensive alternative available
Drug not covered by formulary
Failure to account for pregnancy status, age of patient, or other contraindications

Incorrect nonprescription medication self-prescribed by the patient
Recreational drug use
Wrong Dose
Prescribed dose too high (includes adjustments for renal and hepatic function, age, body size) Correct prescribed dose but overuse by patient (overadherence)
Prescribed dose too low (includes adjustments for age, body size)
Correct prescribed dose but underuse by patient (underadherence)
Incorrect, inconvenient, or less-than-optimal dosing interval (consider use of sustained-release dosage forms)
Adverse Drug Reaction
Hypersensitivity reaction Idiosyncratic reaction
Drug-induced disease
Drug-induced laboratory change
Drug Interaction
Drug–drug interaction Drug–food interaction
Drug–laboratory test interaction
Drug–disease interaction

Subjective and Objective Data

Subjective and objective data in support of a problem are important because assessment of patients and therapies requires the gathering of specific information to verify that a problem continues to exist or that therapeutic objectives are being achieved. Subjective data refer to information provided by the patient or another person that cannot be confirmed independently. This is the data most commonly obtained during a patient interview. Objective data refer to information observed or measured by the practitioner (e.g., laboratory tests, blood pressure [BP] measurements). Objective data are most commonly obtained from the EMR or paper chart (data-rich environment). However, some objective data can be obtained in data-poor environments. In the absence of a medical record, weight, height, pulse, BP, blood glucose readings, and other objective information can be gathered during the provider–patient encounter.

CASE 1-2

QUESTION 1: P.N., a 28-year-old man, has a BP of 140/100 mm Hg. What is the primary problem? What subjective and objective data support the problem, and what additional subjective and objective data are not provided but usually are needed to define this particular problem?

The primary problem is hypertension. No subjective data are given. The objective data are the patient's age, sex, and BP of 140/100 mm Hg. Each of these is important in designing a patient-specific therapy plan. Because hypertension often is an asymptomatic disease (see Chapter 9, Essential Hypertension), subjective complaints such as headache, tiredness or anxiety, shortness of breath (SOB), chest pain, and visual changes usually are absent. If long-term complications such as rupturing of blood vessels in the eye, glomerular damage, or encephalopathy were present, subjective complaints might be blurring or loss of vision, fatigue, or confusion. Objective data would include a report by the physician on the findings of the chest examination (abnormal heart or lung sounds if secondary HF has developed), an ocular examination (e.g., presence of retinal hemorrhages), and laboratory data on renal function (blood urea nitrogen, creatinine, or creatinine clearance). To place these complications in better perspective, the rate of change should be stated. For example, the serum creatinine has increased from a level of 1 mg/dL 6 months ago to a value of 3 mg/dL today. Vague descriptions such as "eye changes" or "kidney damage" are of little value, because progressive damage to these end organs results from uncontrolled high BP, and disease progression needs to be monitored more precisely.

CASE 1-3

QUESTION 1: D.L., a 36-year-old construction worker, tripped on a board at the construction site 2 days ago, sustaining an abrasion of his left shin. He presents to the emergency department with pain, redness, and swelling in the area of the injury. He is diagnosed as having cellulitis. What is the primary problem? What subjective and objective data support the problem? What additional subjective and objective data are not provided but usually are needed to define this particular problem?

The primary problem is cellulitis of the left leg. Useful pieces of subjective information are D.L.'s description of how he injured his shin at a construction site and his current complaints of pain, redness, and swelling. The fact that he was at a construction site is indirect evidence of a possible dirty wound. Further information must be obtained about how he cleaned the wound after the injury and whether he has received a booster dose of tetanus toxoid within the past 10 years. Objectively, the wound is on the left shin. No other objective data are given. Additional data to obtain would be to document the intensity of the redness on a one-to-four-plus scale, the size of the inflamed area as described by an area of demarcation, the circumference of his left shin compared with his right shin, the presence or absence of pus and any lymphatic involvement, his temperature, and a white blood cell count with differential.

CASE 1-4

QUESTION 1: C.S., a 58-year-old woman, has had complaints of fatigue, ankle swelling, and SOB, especially when lying down, for the past week. Physical examination shows distended neck veins, bilateral rales, an S_3 gallop rhythm, and lower extremity edema. A chest radiograph shows an enlarged heart. She is diagnosed as having HF and is being treated with furosemide and digoxin. What is/are the primary problem(s)? What subjective and objective data support the problem(s)? What additional subjective and objective data are not provided but usually are needed to define this (these) particular problem(s)?

The primary problem is systolic HF. Subjectively, C.S. claims to be experiencing fatigue, ankle swelling, and SOB, especially when lying down. She claims to have been taking furosemide and digoxin. An expanded description of these symptoms and her medication use would be helpful. The findings on physical examination and the enlarged heart on chest radiograph are objective data in support of the primary problem of HF. In addition, other objective findings that would help in her assessment would be the pulse rate, BP, serum creatinine, serum potassium concentration, digoxin blood level, a more thorough description of the rales on lung examination, extent of neck vein distension, and degree of leg edema. Pharmacy records could be screened to determine current dosages and refill patterns of the medications.

In this case, a second primary problem may be present. Current recommendations for the management of HF include use of an angiotensin-converting enzyme (ACE) inhibitor before or concurrent with digoxin therapy. Thus, a possible drug-related problem is the inappropriate choice of drug therapy ("wrong drug"). The patient or prescriber should be consulted to ascertain whether an ACE inhibitor has been used previously, any contraindications exist, or possible adverse effects were encountered.

Assessment

After the subjective and objective data have been gathered in support of specific listed problems, the practitioner should assess the acuity, severity, and importance of these problems. He or she should then identify all factors that could be causing or contributing to the problem. The assessment of the severity and acuity is important because the patient expects relief from the symptoms that are of particular concern at this time. During the initial encounter with a patient, it might be discovered that the medical problem is only a symptom complex and that a diagnosis is needed to more accurately identify the problem and further define its severity.

The assessment is usually performed during or immediately after the data gathering, while the provider keeps in mind evidence-based practices. For example, if diabetes is assessed and pertinent subjective data (medication history, social history, diet, exercise, etc.) and objective data exist (laboratory test results like

---

hemoglobin A_{1c}, low-density lipoprotein cholesterol [LDL-C], BP, etc.), then the assessment of diabetes may be to determine whether the patient is meeting the goals for the disease as defined by the ADA. If the patient is not at goal, then the explanation of the reasons why would be described in the assessment, and the plan would then be centered on helping that patient get to goal. Sometimes, the distinction between subjective information provided by the patient and assessments made by the practitioner are confused in the POMR. What the patient reveals belongs in the subjective data, and how the provider interprets it belongs in the assessment. For example, a patient stating that she is having difficulty affording her medications belongs in the subjective information. However, a patient appearing to have cost-related lack of adherence belongs in the assessment, because it is the provider's interpretation of what the patient has stated.

DRUG THERAPY ASSESSMENT

A responsibility of the practitioner is to monitor the response of patients to prescribed therapeutic regimens. The purpose of drug therapy monitoring is to identify and solve drug-related problems and to ensure that all therapeutic objectives are being achieved. Unless proven otherwise, the medical diagnosis should be assumed to be correct. On occasion, the diagnosis may not be readily apparent, or a drug-induced problem may have been diagnosed incorrectly as being a disease entity.

Health care practitioners share the responsibility to assess and monitor patient drug therapy. For the pharmacist, medication reconciliation and the drug therapy assessment may occur in many practice settings, including the community pharmacy while dispensing or refilling prescriptions or counseling patients, during MTMS encounters in the home or in the clinic, while assessing therapy for the hospitalized patient, or as part of routine monthly evaluations of patients residing in long-term care facilities. Many states have enacted legislation allowing pharmacists to develop collaborative drug therapy agreements with physicians for disease state management of common disorders such as asthma, diabetes, dyslipidemia, and hypertension. Additional services commonly provided by pharmacists through collaborative drug therapy agreements include anticoagulation monitoring, emergency contraception, and immunizations.[5] These services often involve more detailed drug therapy evaluation and assessment and may occur within or outside the traditional pharmacy setting. Regardless, the patient's need, time constraints, working environment, and practitioner's skill level govern the extent of monitoring. Similarly, the exact steps used to monitor therapy and the order in which they are executed need to be adapted to a practitioner's personal style. Thus, the examples given in this chapter should be used by the reader as a guide rather than as a recipe in a cookbook.

Plan

The next step in the problem-oriented (i.e., SOAP) approach is to create a plan, which at the minimum should consist of a diagnostic plan and a MAP that includes patient education. The plan is the action that was justified in the assessment. The plan is clear and direct and does not require explanation (this should be explained in the assessment). For example, if a patient is experiencing constipation while taking an opioid pain reliever, the plan would be to recommend a stool softener or stimulant laxative such as docusate sodium. The plan should also include any follow-up that would be necessary as a result of the action taken.

Patient Education

Educating patients to better understand their medical problem(s) and treatment is an implied goal of all treatment plans. This process is categorized as the development of a patient education plan. The level of teaching has to be tailored to the patient's needs, health literacy, willingness to learn, and general state of health and mind. The patient should be taught the knowledge and skills needed to achieve and evaluate his or her therapeutic outcome. An important component of the patient education plan emphasizes the need for patients to follow prescribed treatment regimens.

The POMR will allow the provider to focus on the interview and encounter independent of the site or service offered. The POMR facilitates documentation of the provision of MTMS across multiple sites and services (across the continuum of care).

The next few sections will discuss how to approach MTMS in various clinical settings.

MEDICATION THERAPY MANAGEMENT SERVICES IN THE COMMUNITY PHARMACY OR AMBULATORY SETTING

The core elements of MTMS have been described by the American Pharmacists Association (APhA) and the National Association of Chain Drug Stores (NACDS).[19] According to these organizations, the core elements of MTMS should include the following components:

1. Medication therapy review (MTR)
2. Personal medication record (PMR)
3. Medication action plan (MAP)
4. Intervention or referral
5. Documentation and follow-up

Medication Therapy Review

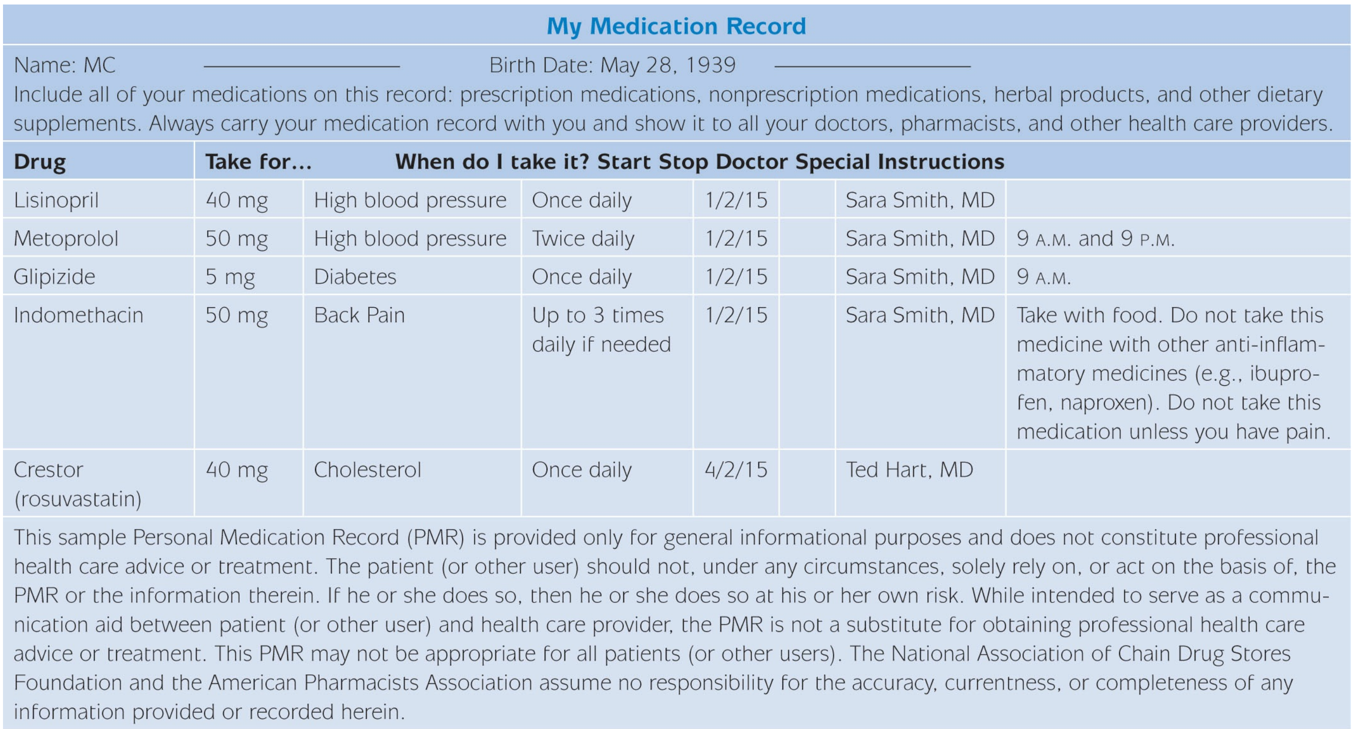
The MTR may be a comprehensive review, including medication reconciliation, in which the provider reviews all of the medications the patient is currently taking, or it may be a focused review of one medication-related issue such as an adverse event. Examples of services provided during the MTR are described in Table 1-6. MTR is dependent on the information that is available from the patient or other data sources.

Table 1-6

Examples of Services Provided During a Medication Therapy Review

- Assess the patient's health status
- Assess cultural issues, health literacy, language barriers, financial status, and insurance coverage or other patient characteristics that may affect the patient's ability to take medications appropriately
- Interview the patient or caregiver to assess, identify, and resolve actual or potential adverse medication events, therapeutic duplications, untreated conditions or diseases, medication adherence issues, and medication cost considerations
- Monitor medication therapy, including response to therapy, safety, and effectiveness
- Monitor, interpret, and assess patient laboratory values, especially as they relate to medication use/misuse
- Provide education and training on the appropriate use of medications
- Communicate appropriate information to other health professionals, including the use and selection of medication therapy

Source: American Pharmacists Association; National Association of Chain Drug Stores Foundation. Medication therapy management in pharmacy practice: core elements of an MTM service model (version 2.0). J Am Pharm Assoc (2003). 2008;48(3):341–353.



My Medication Record

Name: MC ________ Birth Date: May 28, 1939 ________

Include all of your medications on this record: prescription medications, nonprescription medications, herbal products, and other dietary supplements. Always carry your medication record with you and show it to all your doctors, pharmacists, and other health care providers.

Drug		Take for…	When do I take it?	Start	Stop	Doctor	Special Instructions
Lisinopril	40 mg	High blood pressure	Once daily	1/2/15		Sara Smith, MD	
Metoprolol	50 mg	High blood pressure	Twice daily	1/2/15		Sara Smith, MD	9 A.M. and 9 P.M.
Glipizide	5 mg	Diabetes	Once daily	1/2/15		Sara Smith, MD	9 A.M.
Indomethacin	50 mg	Back Pain	Up to 3 times daily if needed	1/2/15		Sara Smith, MD	Take with food. Do not take this medicine with other anti-inflammatory medicines (e.g., ibuprofen, naproxen). Do not take this medication unless you have pain.
Crestor (rosuvastatin)	40 mg	Cholesterol	Once daily	4/2/15		Ted Hart, MD	

This sample Personal Medication Record (PMR) is provided only for general informational purposes and does not constitute professional health care advice or treatment. The patient (or other user) should not, under any circumstances, solely rely on, or act on the basis of, the PMR or the information therein. If he or she does so, then he or she does so at his or her own risk. While intended to serve as a communication aid between patient (or other user) and health care provider, the PMR is not a substitute for obtaining professional health care advice or treatment. This PMR may not be appropriate for all patients (or other users). The National Association of Chain Drug Stores Foundation and the American Pharmacists Association assume no responsibility for the accuracy, currentness, or completeness of any information provided or recorded herein.

This form is based on forms developed by the American Pharmacists Association and the National Association of Chain Drug Stores Foundation. Reproduced with permission from APhA and the NACDS Foundation.

Figure 1-2 Example of a Personal Medication Record (PMR).

Personalized Medication Record

Regardless of the setting, a necessary tool to help with the gathering of the medication information is the PMR. This medication record should be updated after any change in medication therapy and should be shared with other health care providers. The goal of this record is to promote self-care and ownership of the medication regimen.[23] The PMR should be used at all levels of care, thereby facilitating the medication reconciliation process required across the continuum of care. An example of a PMR is shown in Figure 1-2.

Once the patient interview has occurred and the PMR has been updated, the provider may still require information to make an assessment. In such cases, the provider must do his or her best with the available information, or he or she may obtain missing information such as the medical history or objective data from other providers. In some encounters, obtaining the necessary information and medication reconciliation may take the entire visit, necessitating a follow-up encounter.

Medication Action Plan

If adequate information is available to assess the current problem, a MAP should be developed. Because the MAP is patient centered and is prioritized according to the urgency of need, the provider and the patient should develop the plan together. An example of a MAP can be seen in Figure 1-3.

Intervention and Referral

The MAP often describes the intervention performed in an MTM encounter and may serve as documentation that can be shared with the patient and other health care providers (like the PMR). The primary purpose of the MAP is to make the action plan patient centered and to provide the patient with documentation of what they need to do next in the action plan. It also provides space for the patient to document what he or she did related to this action and when it was done. In some instances, the MAP may involve referral to another provider (a physician or pharmacist with additional qualifications) if the issue is beyond the scope of the intervening pharmacist.

Coordination of care is a key element of MTMS and MTR.[1] This may include improving the communication between the patient and other health care providers, enhancing the patient’s understanding of his or her health issues or concerns, maximizing health insurance coverage, advocating on behalf of the patient to get needed medications using available resources and programs, and various other functions that will improve the patient’s understanding of his or her health care environment and promote self-care. Coordination of care may be the primary action taken on behalf of the patient and may be included in the MAP.

Documentation and Follow-up

The development of a documentation process is a necessary component of MTMS.[23] Documentation should be standardized and based on the POMR format. All appropriate records, including the PMR and MAP, should be shared with other providers to promote communication and continuity of care. If the encounter requires follow-up, the documentation should reflect the timing of the follow-up care, and any expectations of the patient and providers should be included. Thorough documentation of the encounter allows all providers to quickly assess the progress of the patient and determine that the desired outcome has been achieved.

An important aspect of documenting the encounter is to submit billing for the encounter when appropriate. Although billing for MTMS is not universally accepted by all payers, the introduction of the national provider identifier (NPI) and pharmacist-specific CPT codes may soon make this a reality.[4,24] The implementation of Medicare Part D in 2006 allowed pharmacists in pharmacies contracted with prescription drug plans to provide MTMS to plan-identified Medicare recipients. Pharmacists bill these plans through the contracted pharmacy by using an NPI and one of three CPT codes. The NPI number designates the provider to be paid, and the CPT determines the amount of payment based on the services rendered. The CPT codes specific to pharmacists providing MTMS include the following:

CPT 99605: Initial face-to-face assessment or intervention by a pharmacist with the patient for 1 to 15 minutes

CPT 99606: Subsequent face-to-face assessment or intervention by a pharmacist with the patient for 1 to 15 minutes

CPT 99607: Each additional 15 minutes spent face-to-face by a pharmacist with the patient; used in addition to 99605 or 99606

Although the NPI number and CPT codes allow pharmacists to bill for MTMS, the reimbursement varies by plan and negotiated contract and is beyond the scope of this text. Pharmacists have also developed patient self-pay reimbursement strategies as well as contracts with self-insured employers and state-run Medicaid programs to provide services.[25,26]

The Patient Protection and Affordable Care Act of 2010 and the Health Care and Education Reconciliation Act of 2010 describe the need for payment reform that promotes improved quality of care. Other providers also see these laws providing new opportunities for pharmacists to participate in care teams such as the patient-centered medical home and pay-for-performance programs to improve medication-related care coordination, quality scores, and patient outcomes.[27,28] The enhanced payment for improving quality in medication-related areas could be used to fund the pharmacist in this activity.

CASE 1-5

QUESTION 1: M.C. is a 76-year-old woman who comes to an appointment at the community pharmacy with her daughter for a focused MTR. She has a Medicare Part D prescription drug plan and is asking for help with her medication costs. She indicates that she has type 2 diabetes, hypertension, back pain, and hyperlipidemia. Her medications include lisinopril 40 mg once daily, metoprolol 50 mg twice daily, glipizide 5 mg once daily, indomethacin 50 mg up to 3 times daily as needed for pain, and rosuvastatin 40 mg once daily. M.C. tells you that she has trouble paying for her rosuvastatin (tier 3, $60 copayment) and would rather have something generic that costs less (tier 1, $5 copayment). Further, she complains of muscle soreness and weakness during the last 3 weeks.

What is the primary problem? What objective information can be obtained in a community pharmacy setting? What additional information is necessary to determine the cause of her problem? How would a clinician assess and document her problem(s) in a SOAP format?

Although the patient presented for a MTR, the primary complaint is the patient's self-reported muscle weakness and soreness during the last 3 weeks. Assuming that M.C. is a patient of this pharmacy, the practitioner could gather the necessary medication history from the PIS. Because the patient is present, this is a good opportunity to develop a PMR with M.C. This process will help to quickly identify any medication discrepancies between the pharmacy computer system and the patient's understanding of medication administration. If discrepancies are noted, the practitioner can clarify them with M.C. right away as part of the intervention. The PMR should also include a section to list medication allergies. The type of reaction should also be included on the PMR so that other providers will know the severity of the medication allergy (i.e., intolerance vs. anaphylactic reaction). Based on the data gathered from the pharmacy computer and M.C., a PMR (depicted in Fig. 1-3) could be developed.

Reviewing the medications alone often does not provide enough information to determine whether M.C. is experiencing a medication-related event. Further questioning related to the onset of her symptoms of muscle soreness and weakness may help to determine whether this is a medication-related problem.

The practitioner can develop an assessment from this questioning and the PMR of the current problem that she is experiencing. As indicated on the PMR, M.C. started rosuvastatin most recently. The initiation of this medication corresponds to the onset of her recent soreness and weakness. β-Hydroxy-β-methylglutaryl-CoA (HMG-CoA) reductase inhibitors like rosuvastatin are known to cause myositis, or muscle breakdown, which may lead to weakness and muscle soreness. Furthermore, the prescribed dose is high for a woman of M.C.'s age. Based on this information, an assessment of the problem can be pursued. If rosuvastatin is the suspected agent, the plan would include actions necessary to solve the problem or to determine whether rosuvastatin is the cause of her muscle soreness and weakness. Unfortunately, not all of the necessary information is available (e.g., her baseline cholesterol, serum creatinine, liver function tests, or creatine kinase levels) to develop a formal plan of action to resolve the adverse medication event. However, part of the plan may be to obtain the laboratory test results necessary to identify or act on the adverse medication event. An example of the documentation of the SOAP note follows.

Primary Problem:

Muscle soreness and weakness (possible adverse medication event).

Subjective:

M.C. reports weakness and soreness, predominantly in her legs during the past 3 weeks. She has difficulty rising from her chair after sitting for long periods and describes the pain as aching. The patient reports taking her medications as prescribed and rarely misses a dose.

Objective:

Total cholesterol: 137 mg/dL; LDL-C: 56 mg/dL;
HDL: 54 mg/dL; Triglycerides: 136 mg/dL
Temperature: 98.5°F
Blood pressure: 144/68 mm Hg

Assessment:

M.C. has muscle weakness and soreness in her large muscle groups. According to the American College of Cardiology and the American Heart Association M.C. is considered to be at risk of heart disease because of her age and concurrent disease states.[29] Her current lipid therapy is rosuvastatin 40 mg once daily, which was started by her cardiologist 6 weeks ago. The initiation of rosuvastatin 40 mg correlates to the timing of her muscle soreness and weakness. HMG-CoA reductase inhibitors (i.e., rosuvastatin) are known to cause myositis or myalgias, and this patient is at particular risk given her age, sex, and starting dose. It is possible that the rosuvastatin could be causing her muscle soreness and weakness. Other lipid-lowering agents could be tried or the dose of rosuvastatin could be reduced, which might eliminate or reduce this adverse event. A creatine kinase level should be obtained to determine the severity of the myositis. A serum creatinine should also be measured, as myositis can lead to renal damage and rhabdomyolysis in severe cases; however, this is usually accompanied by fever and other symptoms that the patient is not currently experiencing.

Plan:

Drug-Related Adverse Event:

- Discussed the possibility of an adverse medication event with the patient, which included the signs and symptoms of myalgias and myositis.

My Medication-Related Action Plan	
Patient:	MC
Doctor (Phone):	Sara Smith, MD
Pharmacy/Pharmacist (Phone):	Rite Mart/Mary John, PharmD
Date Prepared:	May 10, 2015
The list below has important Action Steps to help you get the most from your medications. Follow the checklist to help you work with your pharmacist and doctor to manage your medications AND make notes of your actions next to each item on your list.	
Action steps → What I need to do…	**Notes → What I did and when I did it….**
☐ **For your muscle weakness and soreness** Stop Crestor (rosuvastatin) 40mg. We asked Dr. Hart to change to a lower dose or different agent such as simvastatin. Obtain blood test from Dr. Hart's office. Follow-up with Dr. Hart in 2 days.	
☐ **Medicine Cost** We have asked Dr. Hart to stop Crestor (rosuvastatin) as it is too expensive. A generic medicine such as simvastatin will cost you less and was recommended to Dr. Hart as an alternative. Continue to ask your pharmacist and doctor whether the medications you are taking are covered by your Medicare Part D plan and whether there are any alternatives that may be less expensive.	
☐ **For Pain** Take to Dr. Sara Smith about other pain medications, because the indomethacin may not be the best choice for you due to its side effects/ Some choices might include other medications such as Vicodin (hydrocodone and acetaminophen), over-the-counter acetaminophen, or naproxen or ibuprofen.	
My next appointment with my pharmacist is on: _________ (date) at _________ ☐ AM ☐ PM	
This sample Medication-Related Action Plan (MAP) is provided only for general informational purposes and does not constitute professional health care advice or treatment. The patient (or other user) should not, under any circumstances, solely rely on, or act on the basis of, the MAP or the information therein. If he or she does so, then he or she does so at his or her own risk. While intended to serve as a communication aid between patient (or other user) and health care provider, the MAP is not a substitute for obtaining professional health care advice or treatment. This MAP may not be appropriate for all patients (or other users). The National Association of Chain Drug Stores Foundation and the American Pharmacists Association assume no responsibility for the accuracy, currentness, or completeness of any information provided or recorded herein.	

This form is based on forms developed by the American Pharmacists Association and the National Association of Chain Drug Stores Foundation. Reproduced with permission from APhA and the NACDS Foundation.

Figure 1-3 Example of a Medication Action Plan (MAP).

- Contacted Dr. Hart (M.C.'s cardiologist) to discuss the current problem with rosuvastatin.
- Per discussion with Dr. Hart, will obtain a creatine kinase level and serum creatinine.
- Discontinue rosuvastatin per the pharmacist's recommendation. Dr. Hart agreed that M.C. should temporarily stop her rosuvastatin until her laboratory values are reviewed.
- Alternative dosing of rosuvastatin 5 mg or another equivalent agent (atorvastati 10 mg or simvastatin 20 mg) was discussed with Dr. Hart.
- M.C. is to see Dr. Hart in the cardiology clinic in 2 days to discuss the laborato values and alternative therapies.
- Discussed the entire plan with M.C., and she verbalized understanding of steps that she is to take with respect to her current medication-induced problem.

CASE 1-5, QUESTION 2: From M.C.'s medication profile, what other problems can be identified with her medication therapy? What can be done to address these issues?

There are two remaining issues that may need to be addressed. The first issue relates to the pain medicine (indomethacin) that M.C. is taking. It is suggested that indomethacin may have a higher rate of central nervous system side effects in the elderly compared with other agents in the same class.[30] Furthermore, the American Geriatric Society guidelines on the management of mild-to-moderate persistent pain caution the use of nonsteroidal anti-inflammatory agents in older adults, preferring acetaminophen as a first-line agent.[31] Other prescription medications or nonprescription medication such as acetaminophen alone could be used to help treat M.C.'s pain (see Chapter 55, Pain Management, and Chapter 107, Geriatric Drug Use).

Second, it is not clear from the current information whether the various providers are communicating. It is the responsibility of the pharmacist to help coordinate care among multiple prescribers as described by the APhA MTMS consensus document.[1] Therefore, it is important to be sure that both providers (Drs. Smith and Hart) receive a copy of the documentation of the issues addressed during the visit (SOAP note).

CASE 1-5, QUESTION 3: What additional information can be provided to M.C. at this time?

Finally, M.C. came into the pharmacy asking for help with her medication costs. To assess this problem, it is important to ask whether there are specific cost issues with a particular drug or whether it is her overall medication regimen that causes her concern. Another question to ask is whether she has stopped taking any medications or changed the way she takes them because of cost. Many patients will discuss cost and adherence issues with their pharmacist, because the point of sale for medications occurs at the pharmacy. However, they may not discuss this problem with the prescriber. Cost and lack of adherence because of cost are medication-related problems that the pharmacist must communicate to the prescriber on behalf of the patient. In assessing drug cost, there are several steps that can be taken. First, determine the patient's ability to pay for medications; implement low-cost, medically appropriate interventions targeted to patient needs; facilitate enrollment into relevant benefit programs; and confirm medication changes with the patient and prescribers.

For M.C., the rosuvastatin is her biggest concern, as it costs $60 per month and her Medicare Part D plan lists it as a non-preferred (tier 3) agent on the formulary. With the possible discontinuation of her rosuvastatin, it is important for the pharmacist to anticipate an alternative lipid-lowering agent and determine a cost-effective alternative that may be appropriate. This information can then be relayed to the prescriber. Furthermore, the alternative lipid-lowering formulary choice can be integrated into the plan developed for the primary issue of muscle soreness and weakness (see Case 1-5, Question 1). The integration of multiple problems is a complicated but an important aspect of the MAP.

As discussed previously, an important part of MTMS involves the MAP. The MAP is a document that may empower the patient and promote self-care. The information on the MAP is important for both the patient and the provider, and it facilitates communication among multiple providers. When a patient presents the PMR and MAP to all providers, complex medication information can be shared across the continuum of care. An example of M.C.'s MAP is included in Figure 1-3.

Because extensive information was communicated to the patient and other providers, follow-up (phone or face-to-face) would be appropriate and necessary to determine the resolution to the medication-related issues identified. Follow-up should occur in a timely manner, likely after M.C. has obtained the necessary laboratory test results and has been evaluated by her cardiologist as outlined in the plan. The follow-up should include questions related to the changes that were (or were not) made based on the practitioner recommendations and any new issues that have surfaced. Follow-up should be considered after any encounter in which an action plan is developed to determine whether the medication-related problem has been resolved. Additionally, problems may be identified and prioritized during the initial visit but, because of time constraints, may not be addressed. A follow-up visit allows for assessment of these problems.

CASE 1-5, QUESTION 4: Assuming that the pharmacy provider had an NPI number and a contract with M.C.'s Medicare Part D prescription drug plan, how could the 30 minutes spent with M.C. be billed to her insurance?

Provided that M.C. was identified by her Medicare prescription drug plan as eligible for MTMS, the practitioner could bill for the 30-minute encounter. Using the practitioner's NPI number and the appropriate CPT codes, the practitioner could bill for one CPT 99605 (for the first 15 minutes of initial face-to-face MTM encounter) and one CPT 99607 (for an additional 15 minutes spent with the patient in a face-to-face MTM encounter). M.C.'s Medicare Part D plan may require the practitioner to bill the prescription drug plan initially, and then the plan would pay the community pharmacy directly instead of reimbursing the individual pharmacist. Documentation of the visit would need to be stored at the site of the encounter in case any information was requested from M.C.'s prescription drug plan.

CASE 1-5, QUESTION 5: M.C. has just been hospitalized in a large medical center for renal failure and urosepsis. The pharmacist has access to the medical chart, nursing record, MAR, and a computer that directly links to the clinical laboratory. The pharmacists at this facility assess the patient's drug therapy and routinely provide clinical pharmacokinetic monitoring. How would the pharmacist approach M.C. differently in this inpatient setting compared with the pharmacist in Question 1 who worked in a community pharmacy?

MEDICATION THERAPY MANAGEMENT IN THE ACUTE CARE SETTING

Similar to the outpatient setting, the SOAP format is often used when documenting the encounter of the hospitalized patient; however, obtaining the information needed poses unique challenges. In this setting, subjective information may be more difficult to obtain at the time of assessment in those patients presenting with cognitive impairment resulting from their acute condition, such as the seriously ill or injured patient. Objective data, on the other hand, are more readily available and retrievable with access to pharmacy, laboratory, and other medical record information. On admission to the health care facility, the medication reconciliation process should be initiated to identify any variances in the admission orders when compared with the patient's home medication list. With acute medical problems superimposed on chronic conditions, it is not unusual to have new medications added and home medications held, changed, or discontinued.

Assessing the appropriateness of drug therapy requires a basic understanding of both pharmacokinetic (e.g., absorption, distribution, metabolism, and elimination) and pharmacodynamic (e.g., relief of pain with an analgesic or reduction of BP with an antihypertensive agent) principles. This detailed assessment and monitoring is dependent on the availability of robust patient and laboratory data. The inpatient setting is a relatively data-rich environment in which access to needed information is readily available. Knowledge of the patient's height, body weight, and hepatic and renal function are essential for proper dosage considerations. The type of hospitalized patient will vary from the short-stay elective surgery patient to the critically ill hemodynamically compromised patient. The pharmacist must be aware of how pharmacokinetics and pharmacodynamics can be altered throughout the hospitalization or disease-state process in each patient evaluated. This heightened awareness will allow for timely interventions and minimize medication errors resulting from improper or delayed dosage adjustments because the clinical status of the patient changes. Drug level monitoring may be suitable for certain medications and is of great clinical value; nevertheless, it is important to take into consideration clinical response to drug therapy along with the assessment of a specific laboratory value. Accurate interpretation of any drug level requires review of the nursing MAR (or eMAR), evaluating time of drug administration to serum sample acquisition. When serum drug levels are obtained, they must be reviewed for validity before alterations in medication regimens are made. If a serum drug concentration seems unusually high or low, the clinician

---

must consider all of the various factors that might influence the serum concentration of the drug in that particular patient. When the reason for an unexpected abnormal serum drug concentration is not apparent, the test should be repeated before considering a dose change that may cause supratherapeutic or subtherapeutic concentrations resulting from erroneous data (see Chapter 2, Interpretation of

Clinical Laboratory Tests).

When M.C. was seen in the community pharmacy, the pharmacist assessed her chronic conditions, her cost issues, and her drug therapy. Monitoring in the community pharmacy–based MTM program occurs at regular time intervals and is less sensitive to the day-to-day changes of the patient. However, in the inpatient setting, M.C. has acute conditions (renal failure and urosepsis) in addition to her chronic conditions. Monitoring of medication therapy will occur frequently, resulting in a dynamic treatment plan for her acute and chronic conditions.

Although the inpatient setting is relatively data rich, the information gathered and the assessment and plan formulated in the facility must be communicated to other providers once the patient is discharged. At discharge, it is critical to ensure that the patient has follow-up with his or her primary care physician or coordinated care team in a timely fashion. At this point, it is again critical for the pharmacist to perform medication reconciliation to determine exactly what did happen once the patient returned home. This closes the loop at a critical time when the patient is prone to medication errors and readmission.

MEDICATION THERAPY MANAGEMENT AND PHARMACOGENOMICS

The use of genetic information to predict an individual's response to a drug, known as pharmacogenomics, is currently factoring into drug design and development. Using genetic information to tailor drug therapy to an individual will reduce the risk of adverse events, potentially improve patient outcomes, and create a more efficient drug development process. By transforming drug therapy into a patient-specific approach, the health care community is one step closer to achieving the new medical paradigm of personalized health care.[32]

MTM can be the vehicle to allow pharmacists to serve an integral role in applying pharmacogenomics into clinical practice to improve the quality and safety of health care. Incorporating pharmacogenomics into MTMS allows pharmacists to lend their expertise to the treatment planning process to optimize treatment outcomes. Pharmacists, working collaboratively with prescribers and laboratory facilities, could review medications prescribed for a patient as well as the patient's genomic data to then offer an assessment on whether a prospective drug would provide the best fit for the condition and patient. Through MTMS and pharmacogenomics, pharmacists can optimize drug choice and maximize therapy outcomes (see Chapter 4, Pharmacogenomics and Personalized Medicine).

In order to successfully integrate a pharmacogenomic component within the clinical decision making process, key pharmacogenomic data must be identified. The challenge is complex, and research has begun to bring the application of pharmacogenomics to patients as part of the health care delivery system. The pharmacy profession must define a process for the application of pharmacogenomic data into pharmacy clinical practice that is aligned with MTMS delivery. A viable business model should be developed for these practices that encourages and promotes the use of the clinical expertise of pharmacists working in collaboration with other health care providers and laboratories. The development of technology solutions that support the pharmacist's role in this emerging field should also be encouraged and directed.[32]

CONCLUSION

MTMS are intended to be applicable to patients in all care settings where the patients or their caregivers can be actively involved with managing their medication therapy. The goals of all pharmacists providing MTMS are to confirm that the patient's medication therapy is ideal and that the best possible outcomes from treatment are achieved. The MTM process needs to be properly documented and accurately shared with all providers that are part of the patient's health care team. As drug therapy and technology options continue to evolve, pharmacists are encouraged to provide and optimize MTMS to improve patient outcomes and medication use.

Interpretation of Clinical Laboratory Tests

Erika Felix-Getzik, Yulia A. Murray, and Stefanie C. Nigro

CORE PRINCIPLES	CHAPTER CASES
① Laboratory findings should be used to complement other subjective and objective findings and must not be evaluated in isolation. The values must be assessed in context of the clinical situation and incorporate understanding of human physiology.	**Case 2-3 (Question 1), Case 2-4 (Question 1), Table 2-2 Case 2-5 (Questions 1, 2), Table 2-3, Case 2-6 (Questions 1, 2)**
② Lack of availability, expense, or inconvenience may limit the usefulness of some clinical laboratory tests. Estimations by means of equations or nomograms may be used in clinical practice to overcome these barriers.	**Case 2-1 (Question 1), Table 2-2**
③ Test reliability is impacted by various factors including statistical and preanalytical variations, accuracy, and precision.	**Case 2-1 (Question 1), Case 2-2 (Question 1), Case 2-4 (Question 1), Table 2-1, Table 2-2**
④ Laboratory findings can be helpful in assessing clinical disorders, establishing a diagnosis, assessing drug therapy, or evaluating disease progression.	**Case 2-1 (Question 1), Table 2-2 Case 2-2 (Question 1), Table 2-3 Case 2-3 (Question 1), Case 2-4 (Question 1), Case 2-5 (Questions 1, 2), Case 2-6 (Questions 1, 2)**

This chapter provides the reader with an overview of laboratory tests commonly used in clinical practice. Specialized laboratory tests, which are used to monitor specific disease states or specific drug therapies, are integrated into the case histories, questions, and answers in the disease-specific chapters of this textbook. Over-the-counter or patient-directed laboratory tests are briefly discussed at the end of this chapter because of their increased availability and use. All stated laboratory ranges were obtained from the key references listed at the end of this chapter.[1–3]

GENERAL PRINCIPLES

Generally, laboratory tests should be ordered only if the results of the test will guide decisions about the care of the patient. Serum, urine, and other bodily fluids can be analyzed routinely; however, the economic cost and impact on the quality of life related to obtaining these data must always be balanced by benefit to patient-specific outcomes.

Reference Ranges

The term reference range is typically preferred in clinical practice rather than normal range because there are several factors that contribute to the "normal" value for each individual. Laboratory findings, within and outside the reference range, can be helpful in assessing clinical disorders, establishing a diagnosis, assessing drug therapy, or evaluating disease progression. In addition, baseline laboratory tests are often necessary to evaluate disease progression and response to therapy or to monitor the development of toxicities associated with therapy.

When assessing laboratory findings, it is important to be mindful that values outside the reference range may not require clinical intervention. Values must be assessed in context of the clinical situation and incorporate understanding of human physiology. Likewise, values that fall within the reference range may need further assessment secondary to limitations of the test or impact of biologic or physiologic considerations. Laboratory findings should also be used to complement other subjective and objective findings and must not be evaluated in isolation.

Laboratory test results are specific to the clinical laboratory conducting the test and can vary based on the type of equipment and testing methods used. Consequently, clinicians should rely on reference ranges listed by their own clinical laboratory when assessing laboratory tests.

Evaluating Laboratory Results

The reference ranges provided in this chapter are for general illustrative purposes. When applying this information to the clinical setting, appropriate clinical assessment and judgment should be applied. Patient-specific attributes such as the individual's age, sex, race, clinical presentation, and lifestyle are factors that may influence reported laboratory results and, therefore, must be taken into consideration. Statistical and preanalytical variations are common and must also be evaluated in context of the result obtained. Refer to Table 2-1 for examples of common preanalytical variables.

Test Reliability

As a result of probability, if the same test is completed multiple times on the same sample, typically 1 of 20 results or 5% will be reported outside of the provided reference range. Indicators of test reliability include accuracy, precision, sensitivity, and specificity. Precision refers to the repeatability of a laboratory test (i.e., test results fall within a similar value when repeated), whereas accuracy is the ability of a test to provide a result that is reflective of the "true" value (i.e., the test result matches the actual real value). Quality control and assurance practices at each laboratory are monitored regularly to ensure reliability of results. Typically, if a result is obtained that is significantly outside the reference range, the laboratory will repeat the test to confirm or refute the finding.

Table 2-1

Preanalytical Variation: Factors Affecting the Test Result from the Time the Test Is Ordered Until It Arrives at the Laboratory

Variable	Example(s)
Incorrect test ordered	Albumin ordered to assess impact of recent dietary change (prealbumin better marker for acute changes)
Sample incorrectly labeled	Sample obtained from one patient and labeled with another name
Improper preparation for test	Fasting indicated but not followed: fasting glucose, complete lipid panel Pretest medications not administered in the appropriate manner Pretest diet restrictions not met: rare meat ingested before guaiac test
Medication	Medication interfered with testing procedure or by pharmacologic effect: β-agonist can reduce serum potassium concentrations, thiazides can increase serum uric acid levels
Improper timing of test	Vancomycin trough taken after first dose (rather than before the fourth dose) aPTT measured 2 hours after initial dose (rather than 6 hours after start)
	Fasting glucose test completed shortly after a meal, TSH measured 2 weeks after dose change (rather than 4–6 weeks after change)
Collection incomplete or improper	Abnormal 24-hour urine collection secondary to patient forgetting to void in provided container, blood specimen obtained from extremity with IV infusion site resulting in dilutional effect of glucose, BUN, and electrolytes, specimen collected in incorrect container
Improper handling or storage	Hyperkalemia because of hydrolysis of blood specimen

Poor accuracy or precision	Faulty or outdated laboratory reagents in use
Technical	Result incorrectly read, computer keying error
Sex	Many laboratory findings are sex dependent
Age	Neonatal, pediatric, adult, and geriatric populations have unique reference ranges for numerous laboratory tests
Pregnancy	Gestational status impacts numerous laboratory findings: alkaline phosphatase, cholesterol, iron, etc.
Posture	Being in upright position during laboratory sampling can increase albumin, calcium, iron, etc.
Exercise	Strenuous exercise before testing can impact lactate, creatine kinase, ALT, AST, uric acid, etc.
Normal physiologic fluctuations	Circadian rhythm can impact cortisol, serum iron, serum creatinine, WBC count, etc.
Medical procedures	Blood transfusion with red blood cells before hemoglobin A_{1c} measured results in normal A_{1c} for poorly controlled individual with diabetes, creatine kinase elevated secondary to recent cardioversion

A_{1c}, hemoglobin A_{1c} (also glycosylated hemoglobin); ALT, alanine aminotransferase; aPTT, activated partial thromboplastin time; AST, aspartate aminotransferase; BUN, blood urea nitrogen; IV, intravenous; TSH, thyroid-stimulating hormone; WBC, white blood cell.

Research studies generally establish the sensitivity and specificity of laboratory tests. Clinically, these are essential to distinguish the presence or absence of a disease or condition. Sensitivity is the ability of the test to correctly identify the disease or condition. If a test is 95% sensitive, then 95% of the individuals will be correctly identified as having the disease or condition, but 5% will have a negative test result even though they have the disease or condition (false negative). Specificity is the ability of the test to rule out individuals who do not have the disease or condition. If a test is 95% specific, then 95% of the individuals without disease will have a correct negative result, but 5% will be identified as having the disease or condition even though they are negative (false positive).

Units of Measure

The International System of Units (SI) reports clinical laboratory values using the metric system. The basic unit of mass for the SI system is the mole, which is not influenced by the added weight of salt or ester formulations. Therefore, the mole is technically and pharmacologically more meaningful than the gram because each physiologic reaction occurs on a molecular level. Efforts to implement the SI system internationally for laboratory test reports have been resisted in the United States. Despite adopting SI transition policies in the late 1980s, major American medical journals have since reverted back to the traditional units for laboratory test reporting.[4,5] In this chapter, reference ranges for common laboratory tests are presented in both conventional and SI units, along with “conversion factors” to interchange traditional and SI units (Tables 2-2 and 2-3).

Table 2-2

Blood Chemistry Reference Values

Laboratory Test	**Normal Reference Values**		**Conversion Factor**	**Comments**
	Conventional Units	**SI Units**		
Electrolytes				
Sodium	135–147 mEq/L or mmol/L	135–147 mmol/L	1	Low sodium is usually caused by excess water (e.g., ↑ serum antidiuretic hormone) and is treated with water restriction. ↑ in severe dehydration, diabetes insipidus, significant renal and GI losses
Potassium	3.5–5 mEq/L	3.5–5 mmol/L	1	↑ with renal dysfunction, acidosis, K-sparing diuretics, hemolysis, burns, crush injuries. ↓ by diuretics, alkalosis, severe vomiting and diarrhea, heavy NG suctioning
CO_2 content	21–32 mEq/L	21–32 mmol/L	1	Sum of HCO_3^- and dissolved CO_2. Reflects acid–base balance and compensatory pulmonary (CO_2) and renal (HCO_3^-) mechanisms. Primarily reflects HCO_3^-
Chloride	95–110 mEq/L	95–110 mmol/L	1	Important for acid–base balance. ↓ by GI loss of chloride-rich fluid (vomiting, diarrhea, GI suction, intestinal fistulas, overdiuresis)
BUN	8–20 mg/dL	2.8–7.1 mmol/L	0.357	End product of protein metabolism, produced by liver, transported in blood, excreted renally. ↑ in renal dysfunction, high protein intake, upper GI bleeding, volume contraction
Creatinine	≤1.5 mg/dL	≤133 µmol/L	88.4	Major constituent of muscle; rate of formation constant; affected by muscle mass (lower with aging and gender); excreted renally. ↑ in renal dysfunction. Used as a primary marker for renal function (GFR)
CrCl	90–130 mL/minute	1.5–2.16 mL/s	0.01667	Reflects GFR; ↓ in renal dysfunction. Used to adjust dosage of renally

				eliminated drugs
Estimated GFR	90–120 mL/minute/1.73 m^2	n/a	n/a	Possibly a more accurate reflection of renal function than CrCl. Still influenced by muscle mass
Cystatin C	<1.0 mg/dL	<0.749 µmol/L	0.749	Indicator of renal function—not influenced by patient muscle mass, age, or sex. May also help predict patients at risk for cardiovascular disease
Glucose (fasting)	65–115 mg/dL	3.6–6.3 mmol/L	0.05551	↑ in diabetes or by adrenal corticosteroids
Glycosylated hemoglobin	3.8%–6.4%	3.8%–6.4%	1	Used to assess average blood glucose over 1–3 months. Used to diagnose diabetes, monitor disease progression, and/or assess the efficacy of drug therapy
Calcium—total	8.6–10.3 mg/dL	2.2–2.74 mmol/L	0.250	Regulated by body skeleton redistribution, parathyroid hormone, vitamin D, calcitonin. Affected by changes in albumin concentration. Total calcium ↓ when albumin ↓ (the serum total calcium concentration falls by 0.8 mg/dL for every 1-g/dL fall in serum albumin concentration). ↓ by hypothyroidism, loop diuretics, vitamin D deficiency; ↑ in malignancy and hyperthyroidism
Calcium—unbound (ionized)	4.4–5.1 mg/dL	1–1.3 mmol/L	0.250	Physiologically active form. Unbound “free” calcium remains unchanged as albumin fluctuates
Magnesium	1.3–2.2 mEq/L	0.65–1.1 mmol/L	0.51	↓ in malabsorption, severe diarrhea, alcoholism, pancreatitis, diuretics, hyperaldosteronism (symptoms of weakness, depression, agitation, seizures, hypokalemia, arrhythmias). ↑ in renal failure, hypothyroidism, magnesium-containing antacids
Phosphate (inorganic phosphorus)	2.5–5 mg/dL	0.8–1.6 mmol/L	0.323	↑ with renal dysfunction, hypervitaminosis D, hypocalcemia, hypoparathyroidism. ↓ with excess aluminum antacids, malabsorption, renal losses, hypercalcemia, refeeding syndrome
Uric acid	3–8 mg/dL	<0.42 mmol/L	0.06	↑ in gout, neoplastic, or myeloproliferative disorders, and drugs (diuretics, niacin, low-dose salicylate, cyclosporine)
Proteins				
Prealbumin	19.5–35.8 mg/dL	195–358 mg/L	10	Indicates acute changes in nutritional status, useful for monitoring TPN
Albumin	3.6–5 g/dL	36–50 g/L	10	Produced in liver; important for intravascular osmotic pressure. ↓ in liver disease, malnutrition, ascites, hemorrhage, protein-wasting nephropathy. May influence highly protein-bound drugs

Globulin	2.3–3.5 g/dL	23–35 g/L	10	Active role in immunologic mechanisms. Immunoglobulins ↑ in chronic infection, rheumatoid arthritis, multiple myeloma
CK	Female: 20–170 IU/L Male: 30–220 IU/L	Female: 0.33–2.83 µkat/L Male: 0.5–3.67 µkat/L	0.01667	In tissues that use high energy (skeletal muscle, myocardium, brain). ↑ by IM injections, MI, acute psychotic episodes. Isoenzyme CK-MM in skeletal muscle; CK-MB in myocardium; CK-BB in brain. MB fraction >5%–6% suggests acute MI
CK-MB	<6%	<6%	0.01667	
cTnI	0–0.04 ng/mL	0–0.04 mcg/L	1	More specific than CK-MB for myocardial necrosis; cTnI >0.04 suggests acute myocardial necrosis

Myoglobin	Female: 12–76 mcg/L Male: 19–92 mcg/L	Female: 12–76 mcg/L Male: 19–92 mcg/L	1	Early elevation (within 3 hours) may suggest myocardial injury, but less specific than CK-MB or troponin
Homocysteine	4–12 µmol/L	4–12 µmol/L	1	Damages vessel endothelial, which may increase the risk for cardiac disease. Associated with deficiencies in folate, vitamin B_6, and vitamin B_{12}
LDH	100–250 IU/L	1.67–4.17 mkat/L	0.01667	High in heart, kidney, liver, and skeletal muscle. Five isoenzymes: LD1 and LD2 mostly in heart, LD5 mostly in liver and skeletal muscle, LD3 and LD4 are nonspecific. ↑ in malignancy, extensive burns, PE, renal disease
BNP	<100 pg/mL	<100 ng/L	1	BNP >500 ng/L indicates congestive heart failure. Released from ventricles with ↑ workload placed on heart
NT-proBNP	<60 pg/mL males <150 pg/mL females	<60 ng/L males <150 ng/L females	1	NT-proBNP has similar clinical utility to BNP as a marker for CHF
CRP	0–1.6 mg/dL	0–16 mg/L	1	Nonspecific indicator of acute inflammation. Similar to ESR, but more rapid onset and greater elevation. CRP >3 mg/dL increases risk of cardiovascular disease
hs-CRP	0–2.0 mg/L	0–2.0 mg/L	1	More sensitive measure of CRP; concentrations from 0.5 to 10 mg/L; hs-CRP <1.0 mg/L low risk for cardiovascular disease; 1.0–3.0 mg/L average risk; and >3.0 mg/L high risk for cardiovascular disease
Liver Function				

AST	0–35 units/L	0–0.58 µkat/L	0.01667	Large amounts in heart and liver; moderate amounts in muscle, kidney, and pancreas. ↑ with MI and liver injury. Less liver specific than ALT
ALT	0–35 units/L	0–0.58 µkat/L	0.01667	From heart, liver, muscle, kidney, pancreas. ↑ negligible unless parenchymal liver disease. More liver specific than AST
ALP	20–130 units/L	0.33–2.17 µkat/L	0.01667	Large amounts in bile ducts, placenta, bone. ↑ in bile duct obstruction, obstructive liver disease, rapid bone growth (e.g., Paget disease), pregnancy
GGT				Sensitive test reflecting hepatocellular injury; not helpful in differentiating liver disorders. Usually high in chronic alcoholics
Male	9–50 units/L			
Female	8–40 units/L			
Bilirubin—total	0.1–1 mg/dL	2–18 µmol/L	17.1	Breakdown product of hemoglobin, bound to albumin, conjugated in liver. Total bilirubin includes direct (conjugated) and indirect bilirubin. ↑ with hemolysis, cholestasis, liver injury
Bilirubin—direct	0–0.2 mg/dL	0–4 µmol/L	17.1	
Miscellaneous				
Amylase	35–118 units/L	0.58–1.97 µkat/L	0.01667	Pancreatic enzyme; ↑ in pancreatitis or duct obstruction
Lipase	10–160 units/L	0–2.67 µ kat/L	0.01667	Pancreatic enzyme, ↑ acute pancreatitis, elevated for longer period than amylase
PSA	0–4 ng/mL	0–4 mcg/L	1	↑ in BPH and also in prostate cancer. PSA levels of 4–10 ng/mL should be worked up. Risk of prostate cancer increased if free PSA/total PSA <0.25
TSH	0.5–4.7 µ units/mL	0.5–4.7 munits/L	1	↑ TSH in primary hypothyroidism requires exogenous thyroid supplementation; ↓ TSH in hyperthyroidism
Procalcitonin	<0.5 ng/mL	<0.5 mcg/L	1	↑ Bacterial infections—low risk of sepsis if <0.5 ng/mL; high risk of severe sepsis if >2.0 ng/mL
Total cholesterol	<200 mg/dL	<5.2 mmol/L	0.02586	Current guidelines do not recommend a target level; consult current guidelines
LDL	<100 mg/dL	<2.58 mmol/L	0.02586	Current guidelines do not recommend a target level, but rather starting moderate- to high-intensity statin therapy based on current risk factors; consult current guidelines
HDL	Female: >50 mg/dL	Female: >1.29	0.02586	Current guidelines do not recommend a

	Male: >40 mg/dL	mmol/L Male: >1.03 mmol/L		target level; consult current guidelines
Triglycerides (fasting)	<150 mg/dL	<1.70 mmol/L	0.0113	↑ by alcohol, saturated fats, drugs. Obtain fasting level. Current guidelines do not recommend a target level

ALP, alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; BNP, brain natriuretic peptide; BPH, benign prostatic hypertrophy; BUN, blood urea nitrogen; CHF, congestive heart failure; CK, creatine kinase (formerly known as creatine phosphokinase); CrCl, creatinine clearance; CRP, C-reactive protein; cTnI, cardiac troponin I; ESR, erythrocyte sedimentation rate; GFR, glomerular filtration rate; GGT, γ-glutamyl transferase; GI, gastrointestinal; HDL, high-density lipoprotein; IM, intramuscularly; LDH, lactate dehydrogenase; LDL, low-density lipoprotein; MI, myocardial infarction; NG, nasogastric; PE, pulmonary embolism; PSA, prostate-specific antigen; SI, International System of Units; TPN, total parenteral nutrition; TSH, thyroid-stimulating hormone.

Table 2-3

Hematologic Laboratory Values

	Normal Reference Values		
Laboratory Test	**Conventional Units**	**SI Units**	**Comments**
RBC count			
■ Male	4.3–5.9 × $10^6/\mu L$	4.3–5.9 × $10^{12}/L$	
■ Female	3.5–5.0 × $10^6/\mu L$	3.5–5.0 × $10^{12}/L$	
Hct			↓ with anemias, bleeding, hemolysis. ↑ with polycythemia, chronic hypoxia
■ Male	40.7%–50.3%	0.4–0.503	
■ Female	36%–44.6%	0.36–0.446	
Hgb			Similar to Hct
■ Male	13.8–17.5 g/dL	138–175 g/L	
■ Female	12.1–15.3 g/dL	121–153 g/L	
MCV	80–97.6 μm^3	80–97.6 fL[a]	Describes average RBC size; ↑ MCV = macrocytic, ↓ MCV = microcytic
MCH	27–33 pg	1.66–2.09 fmol/cell	Measures average weight of Hgb in RBC
MCHC	33–36 g/dL	20.3–22 mmol/L	More reliable index of RBC hemoglobin than MCH. Measures average concentration of Hgb in RBC. Concentration will not change with weight or size of RBC
Reticulocyte count (adults)	0.5%–1.5%	0.005–0.015	Indicator of RBC production; ↑ suggests ↑ number of immature erythrocytes released in response to stimulus (e.g., iron in iron-deficiency anemia)

ESR	0–30 mm/hour	0–30 mm/hour	Nonspecific; ↑ with inflammation, infection, neoplasms, connective tissue disorders, pregnancy, nephritis. Useful monitor of temporal arteritis and polymyalgia rheumatica
WBC count	3.8–9.8 × 10^3/μ L	3.8–9.8 × 10^9/L	Consists of neutrophils, lymphocytes, monocytes, eosinophils, and basophils; ↑ in infection and stress
ANC	2,000 cells/μ L		ANC = WBC × (% neutrophils +% bands)/100; if <500 ↑ risk infection, if >1,000 ↓ risk infection
Neutrophils	40%–70%	0.4–0.7	↑ in neutrophils suggests bacterial or fungal infection. ↑ in bands suggests bacterial infection
Bands	0%–10%	0–0.1	
Lymphocytes	22%–44%	0.22–0.44	
Monocytes	4%–11%	0.04–0.11	
Eosinophils	0%–8%	0–0.08	Eosinophils ↑ with allergies, parasitic infections, and certain neoplasms
Basophils	0%–3%	0–0.03	
Platelets	150–450 × 10^3/μ L	150–450 × 10^9/L	<100 × 10^3/μ L = thrombocytopenia; <20 × 10^3/μ L = ↑ risk for severe bleeding
Iron			
■ Male	45–160 mcg/dL	8.1–31.3 μ mol/L	Body stores two-thirds in Hgb; one-third in bone marrow, spleen, liver; only small amount present in plasma. Blood loss major cause of deficiency
■ Female	30–160 mcg/dL	5.4–31.3 μ mol/L	↑ needs in pregnancy and lactation
■ TIBC	220–420 mcg/dL	39.4–75.2 μ mol/L	↑ capacity to bind iron with iron deficiency

ANC, absolute neutrophil count; ESR, erythrocyte sedimentation rate; Hct, hematocrit; Hgb, hemoglobin; MCH, mean corpuscular hemoglobin; MCHC, mean cell hemoglobin concentration; MCV, mean cell volume; RBC, red blood cell; SI, International System of Units; TIBC, total iron-binding capacity; WBC, white blood cell.

[a] fL, femtoliter; femto, 10^{-15}; pico, 10^{-12}; nano, 10^{-9}; micro, 10^{-6}; milli, 10^{-3}.

FLUIDS AND ELECTROLYTES

Please refer to Chapter 27, Fluid and Electrolyte Disorders, for more detailed information.

Sodium

Reference Range: 135–147 mEq/L or mmol/L

Sodium is the predominant cation of the extracellular fluid (ECF), and human cells reside in salt water. Along with chloride, potassium, and water, sodium is important in establishing serum osmolarity and osmotic pressure relationships between intracellular fluid (ICF) and ECF. Osmoregulatory system regulates the plasma sodium concentrations to remain in a normal range by controlling water intake and excretion.[6] An increase in the serum sodium concentration could suggest either impaired sodium excretion or volume contraction. On the contrary, a decrease in the serum sodium concentration to less-than-normal values could reflect hypervolemia, abnormal sodium losses, or sodium starvation. Although healthy individuals are able to maintain sodium homeostasis without difficulty, patients with kidney failure, heart failure, or lung disease often encounter sodium and water imbalances. In adults, changes in serum sodium concentrations most often represent water rather than sodium imbalance. Therefore, serum sodium concentrations are more reflective of a patient's fluid status rather than sodium balance. Clinical manifestations of hyponatremia or hypernatremia are mostly neurologic, and rapid changes in serum sodium concentrations can lead to severe and sometimes fatal brain injury.[6]

HYPONATREMIA

Hyponatremia can result from dilution of the sodium concentration in serum or from a total body depletion of sodium. The finding of hyponatremia implies that sodium has been diluted throughout all body fluids because water moves freely across cell membranes in response to oncotic pressures. Hyponatremia can denote low, high, or normal tonicity. Dilutional hyponatremia is the most common form and results from water retention.[7] Some clinical conditions such as cirrhosis, congestive heart failure (CHF),

---

the syndrome of inappropriate antidiuretic hormone secretion (SIADH), and renal impairment, as well as the administration of osmotically active solutes (e.g., albumin and mannitol) are commonly associated with dilutional hyponatremia. Drugs that can induce SIADH, thereby causing a reversible hyponatremia (especially in the elderly), include cyclophosphamide, carbamazepine, desmopressin, oxcarbazepine, oxytocin, serotonin selective reuptake inhibitors, and vincristine.[7,8] Hyponatremia that results from sodium depletion presents as a low serum sodium concentration in the absence of edema. Sodium-depletion hyponatremia can be caused by mineralocorticoid deficiencies, sodium-wasting renal disease, or replacement of sodium-containing fluid losses with nonsaline solutions.[7] Therapy with thiazide diuretics may also lead to the development of severe hyponatremia. Hyponatremia can be frequently seen in hospitalized patients; however, morbidity varies significantly in severity, and serious complications can be due to the disorder itself or due to the inappropriate management and rapid correction of the sodium levels.

HYPERNATREMIA

Hypernatremia represents a state of relative water deficiency in relation to the body's sodium stores. Because sodium contributes to the cell's tonicity, hypernatremia denotes hypertonicity and at least transient cellular dehydration.[9] Some of the causes of hypernatremia are loss of free water, loss of hypotonic fluid, or excessive sodium intake. Free water loss is uncommon, except in the presence of diabetes insipidus. Diarrhea is the most common cause of hypotonic fluid loss in infants and the elderly. Increased retention of sodium in patients with hyperaldosteronism can also increase serum sodium concentrations. Excessive salt intoxication is usually accidental or iatrogenic and most commonly results from inappropriate intravenous administration of hypertonic salt solutions. Some β-lactam antibiotics (e.g., ticarcillin) contain a modest sodium load and can cause fluid overload when high dosages are administered.

The primary defense against hypertonicity is thirst and subsequent fluid intake. Hypernatremic syndromes, therefore, usually occur in patients who are unable to drink sufficient fluids. For example, demented elderly patients are at increased risk because they depend on others for their water requirements. Similarly, patients who are vomiting, comatose, or not allowed oral fluids are at risk for hypernatremia.

Potassium

Reference Range: 3.5–5.0 mEq/L or mmol/L

Potassium is the most abundant intracellular cation in the body responsible for regulating enzymatic function and neuromuscular tissue excitability. Approximately 90% of the total body potassium is found in the ICF, with the majority in muscle, and only about 10% available in the ECF. The potassium ion in the ECF is filtered freely at the glomerulus of the kidney, reabsorbed in the proximal tubule, and secreted into the distal segments of the nephron. Because the majority of potassium is sequestered within cells, a serum potassium concentration is not a good measure of total body potassium. Intracellular potassium, however, cannot be measured easily. Fortunately, the clinical manifestations of potassium deficiency (e.g., fatigue, drowsiness, dizziness, confusion, electrocardiographic changes, muscle weakness, and muscle pain) correlate well with serum concentrations. The serum potassium concentration is buffered and can be within normal limits despite abnormalities in total body potassium. During potassium depletion, potassium moves from the ICF into the ECF to maintain the serum concentration. When the serum concentration decreases by a mere 0.3 mEq/L, the total body potassium deficit is approximately 100 mEq. Serum potassium concentrations, therefore, can be misleading when interpreted in isolation from other considerations, and assumptions should not be made as to the status of total body potassium concentration based solely on a serum concentration measurement. Disorders of potassium are commonly the result of (1) alterations in intake, (2) alterations with excretion, and/or (3) unbalanced transcellular shifting of potassium (e.g., metabolic acidosis/alkalosis).

HYPOKALEMIA

The kidneys are responsible for about 90% of daily potassium loss (~40–90 mEq/day), and the remaining 10% of potassium is excreted in the stool and a negligible amount in sweat. The kidneys, however, have only a limited ability to conserve potassium. Even when potassium intake has ceased, the urine will contain at least 5 to 20 mEq of potassium per 24 hours. Therefore, prolonged intravenous therapy with potassium-free solutions in a patient unable to obtain potassium in foods (e.g., nothing by mouth) can result in hypokalemia. Hypokalemia can also be induced by osmotic diuresis (e.g., mannitol and glucosuria), use of thiazide or loop diuretics (e.g., hydrochlorothiazide, furosemide, respectively), excessive mineralocorticoid activity, or protracted vomiting. Although the fluid secreted along most of the upper gastrointestinal (GI) tract contains only a modest amount of potassium (i.e., 5–20 mEq/L), vomiting can induce hypokalemia because of the combined effect from decreased food intake, loss of acid, alkalosis, and loss of sodium. The loss of large amounts of colonic fluid through severe diarrhea and/or laxative abuse can cause potassium depletion because fluid in the colon is high in potassium content (i.e., 30–40 mEq/L). Insulin and stimulation of β_2-adrenergic receptors can also induce hypokalemia because both increase the movement of potassium into cells from the ECF. The magnitude of a potassium deficiency is difficult to establish because of the limited presence of potassium in the ECF. Equation 2-1 can be used to estimate the potassium deficit with hypokalemia:

$$\text{Kdeficit (mmol)} = (K_{\text{normal}} - K_{\text{measured}}) \times \text{kg of body weight} \times 0.4 \qquad \text{(Eq. 2-1)}$$

It is also important to note that hypomagnesemia often accompanies hypokalemia, because magnesium is necessary for the shifting of sodium, potassium, and calcium in and out of cells. As a result, hypokalemic individuals not responding to potassium therapy may be refractory to treatment until hypomagnesemia is corrected. Some laboratories omit magnesium from the general electrolyte panel, so this test may need to be specially ordered.

HYPERKALEMIA

Hyperkalemia most commonly results from decreased renal excretion of potassium (e.g., renal failure, renal hypoperfusion, and hypoaldosteronism), excessive exogenous potassium administration, or excessive cellular breakdown (e.g., hemolysis, burns, crush injuries, surgery, and infections). Drug-induced causes include angiotensin converting enzyme inhibitors, angiotensin receptor blockers, aldosterone antagonists, and nonsteroidal antiinflammatory drugs, to name a few. Metabolic acidosis can also induce hyperkalemia because hydrogen ions move into cells in exchange for potassium and sodium. Abnormal potassium concentrations in the serum primarily affect excitability of nerve and muscle tissue (e.g., myocardial tissue). As a result, arrhythmias can be induced by hyperkalemia or hypokalemia. Potassium also affects some enzyme systems and acid–base balance, as well as carbohydrate and protein metabolism.

Carbon Dioxide Content

Reference Range: 21–32 mEq/L or mmol/L

The carbon dioxide (CO_2) content in the serum represents the sum of bicarbonate (HCO_3) and dissolved CO_2 concentrations. The dissolved CO_2 represents a relatively small component of total CO_2 content, making CO_2 essentially a measure of the serum bicarbonate. Chloride and bicarbonate are the primary negatively charged anions that offset the positively charged cations (i.e., sodium and potassium).

Although several buffer systems (e.g., hemoglobin [Hgb], phosphate, and protein) participate in regulating pH within physiologic limits, the carbonic acid–bicarbonate system is the most important. From a clinical standpoint, most disturbances of acid–base balance result from imbalances of the carbonic acid–bicarbonate system. The importance of bicarbonate in maintaining physiologic pH is presented in Chapter 26, Acid–Base Disorders.

Chloride

Reference Range: 95–110 mEq/L or mmol/L

Chloride (Cl^-) is the principal inorganic anion of the ECF; changes in chloride concentration are usually related to sodium concentration in an effort to maintain a neutral charge. Serum chloride has no real diagnostic significance. The relationship between serum concentrations of sodium, bicarbonate, and chloride is described by Equation 2-2, where R represents the anion gap (AG):

$$Cl^- + HCO_3^- + R = Na^+ \qquad \text{(Eq. 2-2)}$$

As with bicarbonate, chloride contributes to maintaining acid–base balance. A decreased serum chloride often accompanies metabolic alkalosis, whereas an increased serum chloride may indicate a hyperchloremic metabolic acidosis. The serum chloride, however, can also be slightly decreased in acidosis if organic acids or other acids are the primary cause of the acidosis. Hyperchloremia, absence of metabolic acidosis, is seldom encountered, because chloride retention is usually accompanied by sodium and water retention. Hypochloremia can result from excessive GI loss of chloride-rich fluid (e.g., vomiting, diarrhea, gastric suctioning, and intestinal fistulas). Because chloride ions are excreted with cations by the kidneys, hypochloremia may also result from significant diuresis.

Anion Gap

Reference Range: 7–16 mEq/L or mmol/L

The R factor, or AG, represents the contribution of unmeasured acids, such as lactate, phosphates, sulfates, and proteins. As displayed in Equation 2-2, a patient's AG is determined by subtracting the primary anions (Cl^- and HCO_3^-) from the primary cation (Na^+). Some clinicians include potassium in this determination and subtract the anions from both major cations (Na^+ and K^+). If potassium is not incorporated in the calculation, a normal AG is typically 5 to 12 mEq/mL. If potassium is considered, a normal AG would be less than 16 mEq/mL.

An elevated AG may be indicative of a metabolic acidosis caused by an increase in lactic acids, ketoacids, salicylic acids, methanol, or ethylene glycol. A low AG may be the result of reduced concentrations of unmeasured anions (e.g., hypoalbuminemia) or from systematic underestimation of serum sodium (e.g., hyperviscosity of myeloma). See Chapter 26, Acid–Base Disorders, for a more detailed discussion of the clinical use of the AG.

Blood Urea Nitrogen

Reference Range: 8–20 mg/dL or 2.8–7.1 mmol/L

Urea nitrogen is a waste product that comes from protein breakdown. It is produced solely by the liver, transported in the blood, and excreted by the kidneys. The serum concentration of urea nitrogen (i.e., BUN) is reflective of renal function because the urea nitrogen in blood is filtered completely at the glomerulus of the kidney and then reabsorbed and tubularly secreted within nephrons. Acute or chronic renal failure is the most common cause of an elevated BUN. Although the BUN is an excellent screening test for renal dysfunction, it does not sufficiently quantify the extent of renal disease. In addition, several nonrenal factors such as unusually high protein intake, disease states that increase protein catabolism (or upper GI bleeding), and glucocorticoid therapy can increase the BUN concentration. Liver disease and low protein diet will lead to lower BUN concentration. A patient's hydration status will also influence BUN; a water deficit tends to concentrate the urea nitrogen, and a water excess dilutes the urea nitrogen. The ratio of BUN to SCr can also be of clinical use. A normal ratio is roughly 15:1. Ratios greater than 20:1 are observed in patients with decreased blood flow to the kidney (e.g., prerenal disease such as dehydration or conditions involving reduced cardiac output) or conditions involving increased protein in the blood (e.g., dietary intake or an upper GI bleed). Situations in which the BUN:SCr ratio is less than 15:1 are seen in patients with renal failure, significant malnourishment (decreased intake of protein), or severe liver disease in which the liver is no longer able to form urea. It is important to note that BUN can change independent of the renal function and therefore SCr is more useful in estimating renal function.

Creatinine

Reference Range: ≤1.5 mg/dL or ≤133 µmol/L

Creatinine is derived from the creatine and phosphocreatine metabolism in the skeletal muscle. Its rate of formation for a given individual is remarkably constant and is determined primarily by an individual's muscle mass or lean body weight. Therefore, the SCr concentration is slightly higher in muscular subjects, but unlike the BUN, it is less directly affected by exogenous factors or liver impairment. Once creatinine is released from muscle into plasma, it is excreted renally almost exclusively by glomerular filtration and is not reabsorbed or metabolized by the kidney. A decrease in the glomerular filtration rate (GFR) results in an increase in the SCr concentration. Thus, careful interpretation of the SCr concentration is used widely in the clinical evaluation of patients with suspected renal disease. However, SCr concentration on its own should not be utilized to assess the level of kidney function in an individual.

A doubling of the SCr level roughly corresponds to a 50% reduction in the GFR. This general rule of thumb only holds true for steady-state creatinine levels.[10]

Of importance, as patients become older, there is a reduction in muscle mass and creatinine production is progressively decreased. Furthermore, the SCr concentration in female patients is generally 0.2 to 0.4 mg/dL (85%–90%) less than for males because females have less muscle mass.

Creatinine Clearance

Reference Range: 90–130 mL/minute

Because creatinine is cleared almost exclusively through the glomerulus in the kidney, creatinine clearance (CrCl) can be used as a clinically useful measure of a patient's GFR. CrCl serves as a valuable clinical parameter because many renally eliminated drugs are dose-adjusted based on the patient's renal function. To determine actual CrCl, the patient's urine is collected for a 24-hour period, and the concentration of urine creatinine (mg/dL), total volume of urine collected during the 24-hour period (mL/minute), and SCr (mg/dL) are determined. The patient-specific measured CrCl is determined using Equation 2-3:

$$\text{CrCl} = U_{\text{creatinine}} \times U_{\text{volume}} \,/\, \text{SCr} \times \text{Time (minutes)} \qquad \text{(Eq. 2-3)}$$

Unfortunately, urine collections are time consuming and expensive, and incomplete collections can substantially underestimate renal function. In lieu of measuring actual CrCl, simplistic equations are commonly used to estimate a patient's CrCl. The following Cockcroft–Gault formula incorporates age, body weight, and SCr.[11] This formula can be utilized to estimate renal function when SCr is stable. Typically, clinicians use ideal body weight (IBW) in the calculation of estimated CrCl; however, actual body weight (ABW) may be used when ABW is less than IBW. Equation 2-4 has the highest correlation and the greatest accuracy in patients with SCr concentrations less than 1.5 mg/dL[12]:

$$\text{Estimated CrCl for males (mL/minute)} = (140 - \text{Age})(\text{Body weight in kg}) \,/\, (72)(\text{SCr}_{(\text{mg/dL})}) \qquad \text{(Eq. 2-4)}$$

The Cockcroft–Gault formula must be multiplied by 85% to calculate CrCl for females to account for the fact that females have less muscle mass.

Another commonly used approach to estimating CrCl is the Jelliffe method[13], shown in Equation 2-5:

$$\text{Estimated CrCl for males (mL/minute/1.73 m}^2) = 98 - [(0.8)(\text{Age} - 20)] \,/\, \text{SCr}_{(\text{mg/dL})} \qquad \text{(Eq. 2-5)}$$

This Jelliffe formula must be multiplied by 90% to calculate CrCl for females. The use of this method substantially underestimates CrCl for patients with SCr values less than 1.5 mg/dL,[13] whereas Cockcroft–Gault appears to have the highest correlation and greatest accuracy in patients with SCr values less than 1.5 mg/dL.[12] For patients with liver dysfunction, all methods of calculating CrCl from an SCr value are associated with significant overpredictions of CrCl.[14] Thus, methods for predicting CrCl should be used cautiously when attempting to adjust drug dosages in patients with liver disease. These equations should not be utilized in patients with rapidly changing GFR (e.g., acute kidney injury) because they will not provide accurate estimates of the GFR.

CASE 2-1

QUESTION 1: A 24-hour CrCl determination was ordered for D.B., a 72-year-old, 62-kg white man. The following data were returned from the clinical laboratory (total collection time was 24 hours):

Total urine volume: 1,000 mL
Urine creatinine concentration: 42 mg/dL
SCr: 2.0 mg/dL

Determine both the measured and the estimated CrCl for D.B. based on the given data, and compare and contrast these results.

Using Equation 2-3, D.B. has a 24-hour measured CrCl of approximately 15 mL/minute. His estimated CrCl is 29.2 mL/minute using the Cockcroft–Gault method (Eq. 2-4). Based on both methods, D.B.'s ability to clear renally eliminated drugs is impaired and adjustments to the dose/frequency will need to be made. An incomplete collection of urine during the 24-hour period or possible mishandling of the specimen can be explanations for the lower value seen with the measured CrCl. Because D.B. had an elevated SCr of 2.0 mg/dL, the accuracy of the Cockcroft–Gault estimation might also be compromised. D.B's baseline SCr will need to be established and if it is determined that SCr of 2.0 mg/dL is corresponding with D.B's baseline, then Cockroft–Gault estimation will hold true; if SCr of 2.0 mg/dL represents an acute change, then Cockroft–Gault equation should not be used to estimate renal function in D.B.

Estimated Glomerular Filtration Rate

An alternative approach to the Cockcroft–Gault method of estimating an adult patient's clearance was developed as part of the Modification of Diet in Renal Disease (MDRD) study and has been referred to as the MDRD Equation.[15] The originally described equation has been modified into an abbreviated format (Eq. 2-6) as follows:

$$\text{Estimated GFR}_{(\text{mL/minute per } 1.73\ \text{m}^2)} = 186 \times (\text{SCr})^{-1.154} \times (\text{Age})^{-0.203} \times (0.742 \text{ if female}) \times (1.212 \text{ if African American}) \qquad \text{(Eq. 2-6)}$$

where SCr is the serum creatinine in mg/dL, age is in years, and the appropriate additional components are included for female or African-American patients. The above equation is applicable to laboratories reporting SCr values that have not been standardized. Starting in 2005, laboratories began standardizing their SCr values using an isotope dilution mass spectrometry to minimize the variation observed in SCr results from different clinical laboratories. In settings in which the SCr results have been standardized, the initial parameter in the MDRD equation is adjusted downward. The following is used to estimate GFR:

$$\text{Estimated GFR}_{(\text{mL/minute per } 1.73\ \text{m}^2)} = 175 \times (\text{SCr})^{-1.154} \times (\text{Age})^{-0.203} \times (0.742 \text{ if female}) \times (1.212 \text{ if African American}) \quad \text{(Eq. 2-7)}$$

When compared with the Cockcroft–Gault approach, MDRD estimations of GFR were more consistent with actual measurements of GFR. However, because both approaches rely on SCr, the influence of muscle mass and dietary intake still must be taken into consideration. In certain patient populations (e.g., obese patients and elderly patients), use of the MDRD can be less accurate, because the MDRD study equation was primarily derived from white subjects with a mean age of 51 years who had nondiabetic renal disease. A more detailed description of the MDRD equation to estimate GFR is addressed in Chapter 28, Chronic Kidney Diseases.

Cystatin C

Although SCr has long been the primary marker for renal function, cystatin C is a relatively new biomarker being investigated as a more precise measure of GFR. Cystatin C is cleared predominantly through the kidneys and is not reabsorbed, and elevated levels are observed in patients with declining renal function. Reference ranges for cystatin C are similar to SCr (≤1.0 mg/L). In contrast to SCr, which is produced from muscle cells, cystatin C is produced by the blood cells and was not expected to be significantly influenced by factors such as muscle mass, diet, age, sex, and race; however, higher levels of cystatin C have been observed in males and patients with higher height and weight, and higher lean body mass. It was also observed that cystatin C levels are increased with age.[16] In addition, increases in serum cystatin C levels tend to occur earlier than increases in SCr, making it possible to detect renal insufficiency in patients at an earlier stage. This is particularly desirable in patients with diabetes, hypertension, or cardiovascular disease who may be at higher risk for the development of renal disease. Cystatin C is also being evaluated as a potential predictor of cardiovascular disease, and preliminary research has also been directed at the role of cystatin C in Alzheimer disease and demyelinating conditions like multiple sclerosis.

Glucose

Reference Range: 65–115 mg/dL or 3.6–6.3 mmol/L (fasting)

The glucose concentration in the ECF is tightly regulated by homeostatic mechanisms to provide body tissues and cells with a ready source of energy. Two endocrine hormones, insulin and glucagon, work synergistically to maintain normal glucose concentrations. Insulin lowers blood glucose concentrations whereas glucagon, along with the counterregulatory hormones epinephrine, cortisol, and growth hormone, raises glucose levels. Because plasma glucose concentrations fluctuate in response to ingestion of meals, most glucose concentrations are measured in either the fasting state or the postprandial state, depending on the type of information desired. Generally, normal glucose values refer to the plasma glucose concentration in the fasting state. The specific laboratory assay of blood sugar determinations must also be considered because different assay methods vary in their specificity and sensitivity to glucose. Glucose testing using whole blood from capillary finger sticks is used in conjunction with blood glucose metering devices for patients with diabetes. Whole blood measurements using these devices are typically 10% to 15% lower than corresponding plasma glucose levels.

GLYCOSYLATED HEMOGLOBIN

Reference Range: 3.8%–6.4%

Hgb is the oxygen-carrying component of the red blood cell (RBC). During the functional life span of RBCs (~4 months), glucose molecules irreversibly bind to Hgb, which results in glycosylated Hgb A1c (A1c). The concentration of A1c reflects a patient's average blood glucose concentration for the life span of circulating RBCs. As a result, measurement of A1c concentrations is useful to diagnose diabetes, monitor disease progression, and/or assess the efficacy of drug therapy. In a patient without diabetes, about 5% of Hgb is glycosylated. To diagnose diabetes, two confirmatory A1c ≥6.5% are needed.[17] Both fasting plasma glucose (FPG) and postprandial glucose contribute variably to the A1c measurement. One study suggests that the higher the A1c (>8.5%), the greater the contribution of FPG to the A1c.[18] As such, the contribution of FPG decreases as the A1c decreases. The American Diabetes Association suggests an A1c of 7% correlates to an estimated average glucose (eAG) of 154 mg/dL. Estimated average glucose can be calculated using the following equation: eAG (mg/dL) = (28.7 − A1c) − 46.7.[17] It has been estimated that for every 1% reduction in A1c, the risk of microvascular complications is reduced by 37% and the risk of acute myocardial infarction (MI) by 14%.[19]

HYPERGLYCEMIA AND HYPOGLYCEMIA

Hyperglycemia and hypoglycemia are nonspecific signs of abnormal glucose metabolism. Diabetes mellitus is the most common cause of hyperglycemia along with suboptimal use of insulin and/or other antidiabetic agents, high carbohydrate dietary intake, physical inactivity, recent illness or infection, and increased emotional stress. Hyperglycemia may be caused or worsened by certain medications such as corticosteroids, niacin (doses >2 g/day), thiazide and loop diuretics, protease inhibitors, atypical antipsychotics, and 3-hydroxy-3-methylglutaryl-coenzyme A

(HMG-CoA) reductase inhibitors (statins). Insufficient carbohydrate intake because of a missed meal is the most common cause of hypoglycemia in a patient receiving insulin or another hypoglycemic medication. In addition to insulin, drug-induced hypoglycemia includes insulin secretagogues, fluoroquinolone antibiotics, and select herbal products.

CASE 2-2

QUESTION 1: T.C., a 68-year-old man, visits his primary care provider to assess control of his type 2 diabetes. His average blood sugar over the past 90 days recorded by his blood glucose monitor is 195 mg/dL. However, T.C.'s Hgb A1c is 9%, which correlates with an eAG of 240 mg/dL. T.C. is confused that these values are different because he routinely ensures his blood glucose machine is calibrated and coded properly. Why is the laboratory average different?

T.C. should not be alarmed with the difference in these values. His blood glucose monitor is likely working properly and adequately measuring his plasma glucose concentrations. However, the monitor may be reflecting a lower average glucose concentration because of the timing of his daily testing for glucose. For example, measuring blood glucose in a fasting state more frequently than after mealtime could contribute to lower average concentrations because fasting values are typically lower than postprandial concentrations. The A1c is more indicative of his average blood sugar control during the past 90 days than the 90-day average recorded by his blood glucose monitor.

Please refer to Chapter 53, Diabetes Mellitus, for more detailed information regarding glucose and Hgb A1c.

Osmolality

Reference Range: 280–300 mOsm/kg or mmol/kg

The osmolality of a solution is a measure of the number of osmotically active ions (i.e., particles present) per unit of solution. It is the total number of particles in the solution, not the weight of the particle or the nature of the particle that determines osmolality. Because 1 mole of a substance contains 6×10^{23} molecules, equimolar concentrations of all substances in the undissociated state exert the same osmotic pressure. A mole of an ionized compound such as Na^+Cl^- contributes twice as many particles in solution as 1 mole of an undissociated compound such as glucose. In most situations, the primary determinants of serum osmolality in the ECF are sodium (and its accompanying anions), glucose, and BUN. If one corrects for the concentrations of glucose and BUN, the serum concentration of sodium closely mirrors the serum osmolality. A useful formula (Eq. 2-8) is as follows:

$$\text{Osmolality} = (2 \times \text{Na}+) + (\text{Glucose}/18) + (\text{BUN}/2.8) \qquad \text{(Eq. 2-8)}$$

Serum osmolality is helpful when evaluating fluid and electrolyte disorders, particularly sodium imbalances. The difference between the measured serum osmolality and the calculated serum osmolality is commonly referred to as the “osmol gap.” Please note that in practice, osmolality and osmolarity are often used interchangeably. The reader is referred to Chapter 27, Fluid and Electrolyte Disorders, for a more detailed discussion of osmolality.

MULTICHEMISTRY PANELS

Frequently, multiple laboratory tests are needed for a given patient. Common clinical laboratory panels include a basic metabolic panel (BMP), comprehensive metabolic panel, electrolyte, hepatic function, and renal function panels (Table 2-4). Clinicians will often use the following abbreviated method to report a BMP in written medical records:

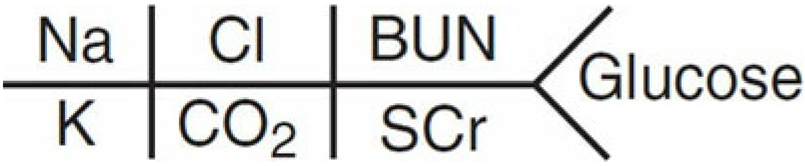

Table 2-4

Common Multichemistry Panels

Laboratory Panels	Electrolyte	BMP	CMP	Hepatic	Renal
Sodium	✓	✓	✓		✓
Potassium	✓	✓	✓		✓
Chloride	✓	✓	✓		✓
CO_2	✓	✓	✓		✓
Glucose		✓	✓		✓
Creatinine		✓	✓		✓
BUN		✓	✓		✓
Calcium		✓	✓		✓
Phosphorous					✓

Multichemistry tests have become routinely used because they quickly provide basic information concerning organ function at relatively low cost. In addition, laboratory automation frequently makes it more cost effective to order a battery of tests within a panel versus a single test. A potential disadvantage of obtaining a battery of tests, however, is that clinicians may be inclined to pursue further laboratory testing when “abnormalities” are not clinically relevant. It is important to note that the individual laboratory tests included in a particular multichemistry panel may vary among clinical laboratories.

Calcium

Reference Range: 8.6–10.3 mg/dL or 2.2–2.74 mmol/L

Calcium has two key physiologic functions within our body; it is an essential intracellular messenger in cells and tissues and a key component of hydroxyapatite, which provides strength, rigidity, and elasticity to the skeleton. All calcium in the body resides primarily in the skeleton, with only about 1% freely exchangeable with that in the ECF. This reservoir of calcium in bones maintains the concentration of calcium in the plasma constant despite pronounced changes in the external balance of calcium. If the homeostatic factors (i.e., parathyroid hormone, vitamin D, and calcitonin) that regulate the calcium content of body fluid are intact, a patient can lose 25% to 30% of total body calcium without a change in the concentration of calcium ion in the plasma.

About 40% of the calcium in the ECF is bound to plasma proteins (especially albumin); 5% to 15% is complexed with phosphate and citrate; and about 45% to 55% is in the unbound, ionized form. Most laboratories measure the total calcium concentration; however, it is the free, ionized calcium concentration that is important and closely regulated physiologically. Most laboratories are also able to measure the ionized form of calcium, which has a reference range of 4.5 to 5.6 mg/dL (1.13–1.4 mmol/L). It is important to obtain an albumin level in patients in order to calculate a corrected calcium level that would account for hypoalbuminemia.

CASE 2-3

QUESTION 1: P.M. is a 61-year-old man admitted status post (s/p) fall because of alcohol intoxication. He has no known drug allergies. P.M’s past medical history is significant for alcohol-induced seizures, alcohol abuse × 20 years, and hypertension. P.M’s laboratory tests revealed the following:

Albumin: 2.0 g/dL
Ca: 6.8 mg/dL
Total bilirubin: 10.8 mg/dL

Serum AST: 280 units/L
Alkaline phosphatase: 240 units/L

Would P.M. be considered hypocalcemic, and how should he be managed?

This case presentation provides insufficient patient data to make a conclusion concerning treatment. However, it does illustrate the importance of treating the patient as a whole, not as a specific laboratory value. Because calcium in the serum is partially bound to plasma proteins (mostly albumin), the serum calcium concentration is affected by the concentration of these plasma proteins. If the albumin concentration is low, the reported serum calcium will generally be less than the lower limit of normal. A useful method to estimate a corrected value for serum calcium in the presence of a low serum albumin is to use the following guideline: the total serum calcium will decrease by 0.8 mg/dL for each decrease of 1.0 g/dL in serum albumin concentration. Thus, evaluating P.M.'s corrected calcium is indicated: $(4 - \text{albumin}_{\text{patient}} \times 0.8) + \text{calcium} = \text{corrected calcium}$. For P.M., his "corrected" serum calcium is 8.4 mg/dL, which is just below the reference range and probably does not warrant treatment with calcium supplementation unless his serum calcium continues to decline. Direct measurement of ionized calcium is independent of albumin concentration, making it unnecessary to correct calcium concentrations in the presence of hypoalbuminemia.

Unfortunately, some clinical laboratories do not have the capability of measuring ionized calcium.

Magnesium

Reference Range: 1.3–2.2 mEq/L or 0.65–1.1 mmol/L

Magnesium is primarily an intracellular electrolyte principally stored in bone and, together with potassium and calcium, helps maintain a neutral charge within the cell. Magnesium also serves an important metabolic role in the phosphorylation of adenosine triphosphate (ATP). Magnesium is necessary for the formation of bone and teeth and for normal nerve and muscle function.

A primary cause of hypomagnesemia is malnourishment. Some other factors associated with hypomagnesemia are use of proton pump inhibitors, chronic diarrhea, alcoholism, and diuretic use. Toxemia in pregnancy is associated with hypomagnesemia. Hypomagnesemia needs to be corrected before attempting to correct hypokalemia or hypocalcemia. Attempts to replace potassium or calcium in patients with hypomagnesemia will be ineffective until the low magnesium concentrations are adequately addressed. Excessive ingestion of magnesium-containing antacids can lead to hypermagnesemia. Increased concentrations of magnesium are also observed in patients with reduced renal function. Hypermagnesemia can slow conduction in the heart, prolong PT intervals, and widen the QRS complex.

Phosphate

Reference Range: 2.5–5 mg/dL or 0.80–1.6 mmol/L

The extracellular concentration of phosphate as inorganic phosphorus is the prime determinant of the intracellular concentration, which in turn is the source of phosphate for ATP and phospholipid synthesis. Intracellular phosphate is also important in the regulation of nucleotide degradation.

The ECF concentration of phosphate is influenced by parathyroid hormone, intestinal phosphate absorption, renal function, bone metabolism, and nutrition. Moderate hypophosphatemia is encountered by malnourished patients (especially when anabolism is induced), patients who excessively use antacids (aluminum-containing antacids bind phosphorus in the GI tract), chronic alcoholics, and septic patients. Clinical consequences of severe hypophosphatemia involve nervous system dysfunction, muscle weakness, rhabdomyolysis, cardiac irregularities, and dysfunction of leukocytes and erythrocytes. Hyperphosphatemia is most commonly caused by renal insufficiency, although increased vitamin D, hypoparathyroidism, and advanced malignancies are also significant causes.

Uric Acid

Reference Range: 3–8 mg/dL or 179–476 μmol/L

Uric acid is an end product of the metabolic breakdown of purines. It is commonly referred to as a metabolically inert compound offering little biologic role. The renal system is responsible for 60% to 70% of total body uric acid excretion. Most uric acid is freely filtered with approximately 90% reabsorbed via the nephron.

Increased serum uric acid concentrations can result from either a decrease in urate excretion (e.g., renal dysfunction) or excessive urate production (e.g., increased purine metabolism resulting from cytotoxic therapy of neoplastic or myeloproliferative disorders). Gout, a common arthritic condition characterized by hyperuricemia, is usually associated with increased serum concentrations of uric acid along with deposits of monosodium urate crystals in joints. Low serum uric acid concentrations are inconsequential and are usually reflective of drugs that have hypouricemic activity (e.g., high dosages of salicylates).

PROTEINS

Prealbumin

Reference Range: 19.5–35.8 mg/dL or 195–358 mg/L

Prealbumin is an important serum protein, but in comparison with other proteins, it accounts for a relatively small percentage of all circulating proteins. It is also referred to as thyroxine-binding prealbumin owing to its role as a transport mechanism for triiodothyronine (T_3) and thyroxine (T_4). However, it is most frequently used to monitor patients at risk for poor nutrition (e.g., patients with eating disorders, patients with human immunodeficiency virus, or patients receiving total parenteral nutrition). Compared with the long half-life of albumin (about 3 weeks), the half-life of prealbumin is only 1 to 2 days. This shorter half-life provides a more accurate reflection of acute changes in protein synthesis, catabolism, and ultimately immediate nutrition status. Hepatic disease and malnutrition are associated with decreases in prealbumin (and albumin). Hodgkin lymphoma, pregnancy, chronic kidney disease, and corticosteroid use can increase prealbumin serum concentrations.

Albumin

Reference Range: 3.6–5 g/dL or 36–50 g/L

Albumin, produced by the liver, contributes approximately 80% to serum colloid osmotic pressure. As a result, hypoalbuminemic states are commonly associated with edema and third spacing of ECF. A lack of essential amino acids from malnutrition or malabsorption, or impaired albumin synthesis by the liver, can result in decreased serum albumin concentrations. Most forms of hepatic insufficiency are associated with decreased synthesis of albumin. It can be lost directly from the blood because of hemorrhage, burns, or exudates or it may be lost directly into the urine because of nephrosis. Serum albumin concentrations seldom increase, but increases may be noted in volume depletion, in shock, or immediately after the administration of large amounts of intravenous albumin. In addition to its diagnostic value, albumin concentration is an important consideration in the therapeutic monitoring of drugs and electrolytes that are highly protein bound (e.g., phenytoin, digoxin, and calcium). In cases of severe hypoalbuminemia, determination of the “free” or unbound concentration of these entities might be necessary for an accurate assessment of drug therapy.

Globulin

Reference Range: 2.3–3.5 g/dL or 23–35 g/L

In addition to albumin, globulin is another primary plasma protein. Whereas albumin principally functions to maintain serum oncotic pressure, globulins play an active role in immunologic processes. The globulins can be separated into several subgroups such as α, β, and γ. The γ-globulins can be separated further into various immunoglobulins (e.g., IgA, IgM, and IgG). Chronic infection or rheumatoid arthritis can increase immunoglobulin levels, and fractionation of immunoglobulins can provide useful information in the evaluation of immune disorders. Because globulin is not manufactured solely by the liver, the ratio of albumin to globulin (the A/G ratio) is changed in patients with liver disease. Changes in this ratio result from decreased albumin concentration and a compensatory increase in globulin concentration.

CARDIAC MARKERS

Cardiac biomarkers are useful for the evaluation, diagnosis, and monitoring of patients with suspected heart damage. These markers, which include some enzymes, are often released into the blood when the myocardium becomes damaged or dies. Enzyme activity is typically expressed in terms of international units, where 1 international unit (IU) is the enzyme amount needed to catalyze the conversion of 1 μmol of substrate per minute. The analogous expression in SI terms involves the term katal (kat). One katal is the amount of enzyme to catalyze 1 mole of substrate per second, making 1.0 μkat the amount for 1.0 μmol/second. Based on this information, the conversion between μkat and IU is 1 μkat = 60 IU.

Creatine Kinase

Reference Range: Female 20–170 IU/L or 0.33–2.83 μkat/L; Male 30–220 IU/L or 0.5–3.67 μkat/L

Creatine kinase (CK), formerly known as creatine phosphokinase, catalyzes the transfer of high-energy phosphate groups in tissues that consume large amounts of energy (e.g., skeletal muscle, myocardium, and brain). The serum concentration of CK can be increased by strenuous exercise, intramuscular injections of tissue-irritating drugs (e.g., diazepam and phenytoin), crush injuries, myocardial damage, rhabdomyolysis, or high doses of certain HMG-CoA reductase inhibitors.

CK is composed of M and B subunits, which are further divided into three isoenzymes: MM, BB, and MB. The CK-MM isoenzyme is found predominantly in skeletal muscle, the CK-BB is predominantly in the brain, and the CK-MB is predominantly in the myocardium. Myocardial CK activity consists of 80% to 85% CK-MM and 15% to 20% CK-MB. Noncardiac tissues that contain large amounts of CK have either CK-MM or CK-BB. The MB fraction is rare in tissues other than the myocardium, making it a more specific cardiac marker.

CK-MB typically begins to increase 3 to 6 hours after an acute MI, peaks at 12 to 24 hours, and accounts for about 5% or more of the total CK.[20] Myocardial damage appears to correlate with the amount of CK-MB released into the serum (i.e., the higher the amount of CK-MB, the more extensive the myocardial injury). Although CK-MB levels greater than 25 units/L are usually associated with an MI, the absolute amount can vary, depending on the assay method.[21] Generally, if the amount of CK-MB exceeds 6% of the total CK, myocardial injury has presumably occurred. Analysis of CK-MB provides a rapid, sensitive, specific, cost-effective, and definitive means of detecting MI.[22]

Troponin

Reference Range: Cardiac Troponin T (cTnT) 0–0.01 ng/mL or mcg/L; Cardiac Troponin I (cTnI) 0.04 ng/mL or mcg/L

Troponins are proteins that regulate the calcium-mediated interaction of actin and myosin within muscles. There are two cardiac-specific troponins, cardiac troponin I (cTnI) and cardiac troponin T (cTnT). Whereas cTnT is present in cardiac and skeletal muscle cells, cTnI is present only in cardiac muscle.[23,24] Compared with the detection of CK-MB, the presence of troponin I is a more sensitive and specific indicator of myocardial necrosis.[25] The concentration of cTnI increases within 2 to 4 hours of an acute MI, enabling clinicians to quickly initiate appropriate therapy. Troponin also remains elevated for about 10 days compared with the 2- to 3-day elevation typically observed with CK-MB. cTnI levels >0.04 ng/mL are suggestive of acute myocardial tissue necrosis, but this value may vary slightly by assay (because of lack of standardization) and by institution. The reader is referred to Chapter 13, Acute Coronary Syndrome, for a more detailed discussion of the use of cardiac markers.

CASE 2-4

QUESTION 1: K.J., a 55-year-old man, with a history of stable angina presents to a hospital emergency department. He complains of sudden-onset chest pressure and tightness, diaphoresis, and nausea that has been waxing and waning for the last few hours. K.J. describes his discomfort as severe at times and not relieved by position change, antacids, or sublingual nitroglycerin. An electrocardiogram reveals ST segment depressions consistent with myocardial ischemia. His cardiac biomarkers reveal: CK 200 IU/L, CK-MB 5%, and cTnI 0.67. K.J. is diagnosed with an MI (non–ST segment-elevation MI) and is admitted for a cardiac catheterization. Why are the total CK and CK-MB serum concentrations within the reference range despite clear evidence, including elevated cTnI, supporting an acute MI?

Although CK and CK-MB are very helpful laboratory values for identifying and assessing myocardial damage/necrosis, the utility of these values alone can be quite limited. Troponin levels are very sensitive and specific to myocardial cell death and can become positive sooner than CK and CK-MB and will remain elevated for a much longer time frame (up to 10 days). So even if the CK and CK-MB are not elevated, the troponin can pick up even the smallest amount of myocardial cell death. Based on the clinical picture and the elevated troponin, the patient would be classified as having a non–ST segment-elevation MI.

Myoglobin

Reference Range: Female 12–76 mcg/L; Male 19–92 mcg/L

Myoglobin, a protein in heart and skeletal muscle cells, provides oxygen to working muscles. Damaged muscle releases myoglobin into the bloodstream. As a cardiac biomarker, myoglobin concentrations in serum rise within 3 hours of insult to the myocardial tissue, peak in about 8 to 12 hours, and return to normal in about a day. Because myoglobin serum concentrations rise more quickly than CK-MB after myocardial injury, they can be of value in helping rule out MI in the emergency department. Myoglobin serum concentrations, however, tend to be less specific for myocardial tissue compared with CK-MB and troponin; trauma or ischemic injury to noncardiac tissue can also increase serum myoglobin.

Homocysteine

Reference Range: 4–12 µmol/L

Patients with deficiencies in folate, vitamin B_6, or vitamin B_{12} tend to have elevated serum levels of homocysteine. Homocysteine is believed to have a destructive effect on vascular epithelium. With time, patients with elevated homocysteine levels (>12 µmol/L) are believed to be at increased risk for cardiac disease.[26] Screening individuals with a positive family history for elevated homocysteine or those with premature atherosclerosis without typical risk factors has been advocated. Understanding the association between increased homocysteine levels and specific vitamin deficiencies, supplementation of folate, vitamin B_6, and vitamin B_{12} has been used clinically. However, data are too limited to suggest that this approach reduces the incidence of acute MI or stroke.

Lactate Dehydrogenase

Reference Range: 100–250 IU/L (adult) or 1.67–4.17 µkat/L

The enzyme lactate dehydrogenase (LDH) is present in the heart, kidney, liver, and skeletal muscle. It is also abundantly present in erythrocytes and lung tissue. Because increased serum concentrations of LDH can be associated with diseases in many different organs and tissues, the diagnostic usefulness of

---

an LDH determination is somewhat limited. There are, however, five isoenzymes of LDH. Although most tissues contain all five isoenzymes, some tissues have a predominance of one of the isoenzymes. LDH_1 and, to a lesser extent, LDH_2 predominate in the heart. Skeletal muscle and the liver have a predominance of LDH_5. LDH_3 and LDH_4 are found in a variety of tissues, including the lungs, RBCs, kidneys, brain, and pancreas. Consequently, identifying specific isoenzymes can increase the diagnostic usefulness of serum LDH determinations.

Brain Natriuretic Peptide

Reference Range: <100 pg/mL or <100 ng/L: >500 pg/mL or >500 ng/L is considered elevated

Brain natriuretic peptide (BNP) is released from the ventricles because of increased myocardial demand. Elevations in BNP are indicative of patients with CHF and volume overload. In an effort to reduce workload on the heart, BNP counteracts the renin–angiotensin–aldosterone system and causes vasodilatory effects, along with natriuresis (increased excretion of sodium), all geared at reducing blood volume. Patients with some degree of CHF typically have BNP levels greater than 100 ng/L. BNP levels greater than 500 ng/L represent definite CHF, but further evaluation is warranted to more fully characterize the extent of impaired cardiac function.[27] More recently, N-terminal proBNP (NT-proBNP), a by-product from the cleaving of pro-BNP to form BNP, is also being used in the clinical setting. BNP has also been used as a tool for patients presenting to the emergency department with severe dyspnea; however, studies have not demonstrated additional benefits associated with using BNP to guide therapy or to use BNP as a criterion for admission. The reader is referred to Chapter 14, Heart Failure, for a more detailed discussion of the use of BNP.

C-Reactive Protein

Reference Range: 0–1.6 mg/dL or 0–16 mg/L

C-reactive protein (CRP) is a nonspecific, acute-phase reactant helpful in the diagnosis and monitoring of inflammatory processes (e.g., rheumatoid arthritis and bacterial infections). CRP is produced by the liver in response to inflammation.

Although an elevation in CRP indicates the presence of an acute inflammatory event, the nonspecific nature of the test does little to identify the cause or location of the inflammation. CRP is similar to an older test, the erythrocyte sedimentation rate (ESR), but it tends to be more sensitive than ESR and is also associated with a more rapid and greater response to acute inflammation. A potential use of CRP is as a novel risk factor for cardiovascular disease.[28] A more sensitive test for CRP is now available and is referred to as hs-CRP or high-sensitivity CRP. The hs-CRP test measures the same acute-phase reactant, but it is able to detect much lower levels of CRP, making it useful for early detection of patients at risk of cardiovascular diseases. Cardiovascular risk assessment is stratified based on the following criteria: patients with hs-CRP values less than 1.0 mg/L have a low risk; patients with an hs-CRP between 1.0 and 3.0 mg/L have an average risk; and patients with an hs-CRP greater than 3.0 mg/L are considered to be at high risk. It is important to realize that although hs-CRP is a new indicator for cardiovascular disease risk, evaluation of other well-established patient risk factors are still the gold standard and must be taken into consideration to determine the patient's overall risk of cardiovascular disease. CRP has also been used to assess chronic inflammatory diseases such as rheumatoid arthritis and Crohn disease. Additionally, because viral infections do not typically increase CRP serum concentrations, the use of CRP as a diagnostic tool to differentiate viral from bacterial infections might be clinically helpful.

LIVER FUNCTION TESTS

Aspartate Aminotransferase

Reference Range: 0–35 units/L or 0–0.58 μkat/L

The aspartate aminotransferase (AST) enzyme is abundant in heart and liver tissue and moderately present in skeletal muscle, kidney, and pancreas. In cases of acute cellular injury to the heart or liver, the enzyme is released into the blood from the damaged cells. In practice, AST determinations have been used to evaluate myocardial injury and to diagnose and assess the prognosis of liver disease resulting from hepatocellular injury. The serum AST level is increased in more than 95% of patients after an MI. However, the increase in AST does not occur until 4 to 6 hours after the onset of myocardial injury. Peak AST concentrations are seen in the serum after 24 to 36 hours, returning to the normal range in about 4 to 5 days.

Serum AST values are elevated significantly in patients with acute hepatic necrosis, whether caused by viral hepatitis or a hepatotoxin (e.g., carbon tetrachloride). In these situations, the serum concentrations of both AST and alanine aminotransferase (ALT) will be increased, even before the appearance of clinical symptoms (e.g., jaundice). The AST and ALT serum concentrations can be increased by as much as 100 times the usual upper limits of normal in the presence of parenchymal liver disease. Patients with intrahepatic cholestasis, posthepatic jaundice, or cirrhosis usually experience more moderate elevations of AST, depending on the extent of cell necrosis. The AST serum concentration is usually higher than that of ALT in patients with cirrhosis, and the AST increase is usually about four to five times greater than the upper limit of normal.

Alanine Aminotransferase

Reference Range: 0–35 units/L or 0–0.58 µkat/L

The ALT enzyme is found in essentially the same tissues that have high concentrations of AST. However, elevations in serum ALT are more specific for liver-related injuries or diseases. Although ALT is relatively more abundant in hepatic tissue versus cardiac tissue than AST, the liver still contains 3.5 times more AST than ALT. Serum concentrations of both AST and ALT increase when disease processes affect liver cell structure, but ALT concentrations are not significantly increased as a result of an acute MI. Evaluating the ratio of ALT to AST can be potentially useful, particularly in the diagnosis of viral hepatitis. The ALT/AST ratio frequently exceeds 1.0 with alcoholic cirrhosis, chronic liver disease, or hepatic cancer. However, ratios less than 1.0 tend to be observed with viral hepatitis or acute hepatitis, which can be useful when diagnosing liver disease.

Alkaline Phosphatase

Reference Range: 20–130 units/L or 0.33–2.17 µkat/L

The alkaline phosphatases (ALPs) constitute a large group of isoenzymes that play important roles in the transport of sugar and phosphate. These isoenzymes of ALP have different physiochemical properties and originate from different tissues (e.g., liver, bone, placenta, and intestine). In normal adults, ALP is derived primarily from liver and bone. Although only small amounts of ALP are present in the liver, this enzyme is secreted into the bile, and substantially elevated ALP serum concentrations can be seen with mild intrahepatic or extrahepatic biliary obstruction. Thus, the presence of early bile duct abnormalities can result in elevated ALP before increases in the serum bilirubin are observed. Drug-induced cholestatic jaundice (e.g., chlorpromazine or sulfonamides) can increase serum ALP concentrations. In mild cases

---

of acute liver cell damage, ALP levels are seldom elevated. Even in cirrhosis, ALP concentrations are variable and depend on the degree of hepatic decompensation and obstruction.

The osteoblasts in bone produce large amounts of ALP, and marked serum elevations can be seen in Paget disease of the bone, hyperparathyroidism, osteogenic sarcoma, osteoblastic cancer metastatic to bone, and other conditions of pronounced osteoblastic activity. The serum ALP is increased during periods of rapid bone growth (e.g., infancy, early childhood, and healing bone fractures) and during pregnancy because of the contributions of the placenta and fetal bones.

Gamma-Glutamyl Transferase

Reference Range: male 9–50 units/L, female 8–40 units/L

Although the enzyme γ-glutamyl transferase (GGT) is found in the kidney, liver, and pancreas, its major clinical value is in the evaluation of hepatobiliary disease. An increase in the serum concentration of GGT parallels the increase of ALP in obstructive jaundice and infiltrative disease of the liver. However, increased ALP in the presence of a normal GGT is more suggestive of muscular or bone-related issues. GGT is one of the more sensitive liver enzymes for identifying biliary obstruction and cholecystitis. Because GGT is a hepatic microsomal enzyme, tissue concentrations increase in response to microsomal enzyme induction by alcohol and other drugs (e.g., carbamazepine, phenobarbital, and phenytoin). As a result, GGT is a sensitive indicator of recent or chronic alcohol exposure.

Bilirubin

Total Bilirubin—Reference Range: 0.1–1.0 mg/dL or 2–18 µmol/L Direct (Conjugated) Bilirubin—Reference Range: 0–0.2 mg/dL or 0–4 µmol/L

Bilirubin is primarily a breakdown product of Hgb and is formed in the reticuloendothelial system (Fig. 2-1, step 1). It is then transferred into the blood (step 2), where it is almost completely bound to serum albumin (step 3). When bilirubin arrives at the sinusoidal surface of the liver cells, the free fraction is rapidly taken up into the cell (step 4) and converted primarily to bilirubin diglucuronide (step 5). A monoglucuronide is also formed that is metabolized predominantly to the diglucuronide. The conjugated bilirubin diglucuronide is then excreted into the bile (step 6) and appears in the intestine, where bacteria convert most of it to urobilinogen (step 7). The majority of urobilinogen is destroyed or excreted in the feces (step 13), but a small portion is reabsorbed into the blood (step 8) and either reabsorbed into the liver (step 9) and subsequently excreted into the bile (step 12) or excreted into the urine (step 10). Urobilinogen is responsible for the straw color of the urine and the yellowish-brown color of the feces. The mechanism by which conjugated bilirubin in the liver cell is transferred to the blood (step 14) is not well understood. However, in many types of liver disease, conjugated (direct) bilirubin is present in increased concentrations in the blood. When this concentration exceeds 0.2 to 0.4 mg/dL, bilirubin will begin to appear in the urine (step 11). Unconjugated (indirect) bilirubin is water insoluble and is highly bound to serum albumin; both factors account for its lack of excretion in the urine.[29]

MISCELLANEOUS TESTS

Amylase and Lipase

Amylase (reference range: 35–118 units/L or 0.58–1.97 µkat/L) and lipase (reference range: 10–160 units/L or 0–2.67 µkat/L) are enzymes produced by the pancreas and secreted into the duodenum to assist in the digestive process. Small amounts of both enzymes are also found in the saliva and stomach. Significantly elevated levels of either enzyme are suggestive of pancreatic damage.

Figure 2-1 Bilirubin metabolism.

Amylase is responsible for breaking down complex carbohydrates into simple sugars. Significant elevations in serum amylase are observed in patients with acute pancreatitis or pancreatic duct obstruction. Amylase levels tend to rise 6 to 48 hours after onset of the disease and usually return to normal 3 days after the acute event. In chronic pancreatitis or obstruction, amylase levels may remain elevated for longer periods. Other nonpancreatic conditions (e.g., bowel perforation, biliary disease, perforated peptic ulcer, ectopic pregnancy, and mumps) can be associated with elevated serum amylase levels.

Lipase is responsible for breaking down triglycerides into fatty acids. Elevated serum lipase levels are also suggestive of pancreatic disease and tend to be more specific for pancreatic disease than amylase. Nonpancreatic conditions such as gallbladder disease or biliary cirrhosis can also lead to elevated lipase levels. The onset of lipase elevation is similar to amylase; however, lipase typically remains elevated for 5 to 7 days and can be useful in diagnosing patients in later stages of pancreatic disease. Narcotics (e.g., morphine) can constrict the sphincter of Oddi and increase serum concentrations of both amylase and lipase.

Prostate-Specific Antigen

Reference Range: 0–4 ng/mL or 0–4 mcg/L

Prostate-specific antigen (PSA) is a protease glycoprotein produced almost exclusively by prostate epithelial cells. Large quantities of PSA are carried in semen; only low levels are found in the blood. Serum concentrations of PSA are increased when

---

the normal prostate glandular structure is disrupted by benign or malignant tumor or inflammation (prostatitis). More than half of men with benign prostatic hyperplasia (BPH) have elevated serum PSA concentrations. PSA is also a valuable parameter for staging and monitoring the progression and response to therapy of prostate cancer.[30]

The prostate gland increases in size with age; therefore, it is expected that older men will have higher PSA levels compared with younger men. PSA serum concentrations can also increase after prostatic manipulation such as digital rectal examination (DRE), catheter placement, transrectal ultrasound, cystoscopy, or biopsy of the prostate. In addition, serum PSA will increase 24 to 48 hours after ejaculation. Although elevated serum concentrations of PSA can occur in men with BPH, concentrations tend to be higher and encountered more often in men with cancer. Men with PSA levels between 4 and 10 ng/mL should be evaluated further for potential prostate cancer.

The serum half-life of PSA is 2 to 3 days, but serum PSA concentrations can remain high for several weeks after manipulation of the prostate. Circulating serum

PSA is bound to plasma proteins, and the capability exists to measure both total and free (unbound) PSA concentrations. Increased risk of prostate cancer has been observed in men with a free PSA to total PSA ratio of less than 0.25.[31] An aggressive approach to localize prostate cancer for men with life expectancies more than 10 years is now favored.[30,32]

Thyroid-Stimulating Hormone

Reference Range: 0.5–4.7 μunits/mL or munits/L

Thyroid-stimulating hormone (TSH, also known as thyrotropin) is secreted by the pituitary gland to stimulate the thyroid gland to produce the thyroid hormones T_4 and T_3. TSH is measured, often in conjunction with the thyroid hormones, to diagnose thyroid disorders and to monitor exogenous thyroid supplementation therapy. The reader is referred to Chapter 52, Thyroid Disorders, as it provides a more detailed discussion of the clinical implications of altered thyroid laboratory findings.

Procalcitonin

Procalcitonin is a precursor for calcitonin and is typically undetectable in healthy individuals. Elevations in procalcitonin occur in patients with inflammation secondary to bacterial infections; however, a similar increase is not observed in patients with inflammation secondary to viral infections or noninfectious conditions. Interestingly, increases in calcitonin are not seen in patients with elevated procalcitonin. In patients with sepsis or sepsis syndrome, procalcitonin levels <0.5 ng/mL have been associated with a low risk of progression to severe sepsis and levels >2.0 ng/mL represent a high risk for severe sepsis. Trials involving lower respiratory tract infections have suggested that antibiotic therapy should be discouraged in patients with procalcitonin levels <0.25 ng/mL, but encouraged for those with levels ≥0.5 ng/mL. These criteria have also been used as a guide for discontinuing therapy as infections resolve; however, the exact role for the use of procalcitonin levels has not been clearly characterized. Additional trials will help to accurately define the role of procalcitonin testing.

Cholesterol and Triglycerides

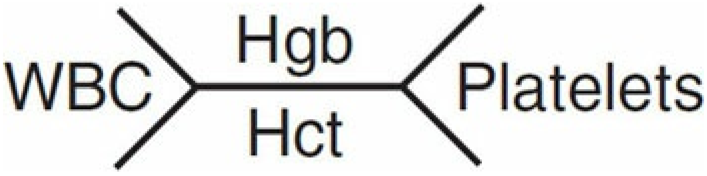
A detailed discussion of hypercholesterolemia and lipid disorders is provided in Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease. For convenience, the current range of desired values for total cholesterol (TC), low-density lipoproteins (LDLs), high-density lipoproteins (HDLs), and fasting triglycerides (TGs) has been incorporated in Table 2-2.

HEMATOLOGY

There are several different hematologic cell types that originate from the hematopoietic stem cell. Each cell line has a defined role and unique contribution to the overall homeostatic process and may be found in the bone marrow, lymph system, or blood. Typically, routine clinical laboratory testing involves measuring concentrations of mature myeloid cells found in the blood. Figure 2-2 illustrates the various lineages derived from the hematopoietic stem cell.[33] The cells derived from the myeloid linage are the focus of the following discussion. Readers are encouraged to refer to Section 16, Hematology and Oncology, to gain further understanding of the clinical relevance of lymphoid and myeloid cells (Fig. 2-2).

Complete Blood Count

The complete blood count (CBC) is one of the most commonly ordered clinical laboratory tests. A CBC measures the RBCs, Hgb, hematocrit (Hct), mean cell volume (MCV), mean cell Hgb concentration (MCHC), and total white blood cells (WBCs). Depending on the laboratory, an order for a CBC may also include platelets, reticulocytes, or leukocyte differential. An abbreviated method of noting hematologic parameters in clinical practice is noted in the following figure.



Red Blood Cells (Erythrocytes)

Males—Reference Range: $4.3–5.9 \times 10^6/\mu L$ or $4.3–5.9 \times 10^{12}/L$
Females—Reference Range: $3.5–5 \times 10^6/\mu L$ or $3.5–5 \times 10^{12}/L$

Erythrocytes or RBCs are produced in the bone marrow, released into the peripheral blood, circulated for approximately 120 days, and cleared by the reticuloendothelial system. The primary function of RBCs is to transport oxygen linked to Hgb from the lungs to tissues. The concentration of RBCs in the blood can be measured to detect anemia, calculate RBC indices, or calculate the Hct. Hct and Hgb concentrations are generally used to monitor quantitative changes in RBCs.

Hematocrit

Males—Reference Range: 40.7%–50.3% or 0.4–0.503
Females—Reference Range: 36%–44.6% or 0.36–0.446

Hct (packed cell volume) is the percentage of RBCs to the total blood volume and is determined by centrifuging a capillary tube of whole blood and comparing the height of the settled RBCs to the height of the column of whole blood. A decrease in Hct may result from bleeding, the bone marrow suppressant effects of drugs, chronic diseases, genetic alterations in RBC morphology, or hemolysis. An increase in Hct may result from hemoconcentration, polycythemia vera, or polycythemia secondary to chronic hypoxia.

Hemoglobin

Males—Reference Range: 13.8–17.5 g/dL or 138–175 g/L
Females—Reference Range: 12.1–15.3 g/dL or 121–153 g/L

Hgb is the major oxygen-carrying compound contained in RBCs. Therefore, total Hgb concentration primarily depends on the number of RBCs in the blood sample. As mentioned with Hct, medical conditions that impact the number of RBCs will also affect Hgb concentration. As discussed previously, glycosylated Hgb (A_{1c}) is a related test used to monitor diabetes mellitus.

Red Blood Cell Indices

RBC indices (also known as Wintrobe indices) are useful in the classification of anemias. These indices include the MCV, the mean cell Hgb (MCH), and the MCHC. These indices are calculated in Equations 2-9 to 2-11:

$$\text{MCV} = \text{Hct (\%)} \times 10 \,/\, \text{RBC (in millions}/\mu\text{L)} = 80 - 97.6 \text{ (in } \mu\text{m}^3 \text{ or fL)} \qquad \text{(Eq. 2-9)}$$

$$\text{MCH} = \text{Hgb (in g/dL)} \times 10/\text{RBC (in millions}/\mu\text{L)} = 27 - 33 \text{ (in pg)} \qquad \text{(Eq. 2-10)}$$

$$\text{MCHC} = \text{Hgb (in g/dL)} \times 100/\text{Hct (\%)} = 33 - 36 \text{ (in g/dL)} \qquad \text{(Eq. 2-11)}$$

MEAN CELL VOLUME

The MCV detects changes in cell size. A decreased MCV indicates a microcytic cell, which can result from iron-deficiency anemia or anemia of chronic inflammation. A large MCV indicates a macrocytic cell, which can be caused by a vitamin B_{12} or folic acid deficiency. Underlying disease states (e.g., habitual alcohol ingestion, chronic liver disease, anorexia nervosa, hypothyroidism, reticulocytosis, and hematologic disorders) may also present with an elevated MCV secondary to deficiencies in these vitamins.[34] The MCV can be normal in a patient with a “mixed” (microcytic and macrocytic) anemia. Note that a direct assessment of a blood smear by a microscopic examination is the gold standard for confirming RBC size.

MEAN CELL HEMOGLOBIN

The MCHC is a more reliable index of RBC Hgb than MCH. MCH measures the weight of Hgb in the RBCs in a sample and MCHC measures concentration of the RBCs contained within a sample. In normochromic anemias, changes in the size of RBCs (MCV) are associated with corresponding changes in the weight of Hgb (MCH), but the concentration of Hgb (MCHC) remains normal. Changes in the Hgb content of RBCs alter the color of these cells. Thus, hypochromic refers to a decrease in RBC Hgb, reflected by reduced MCHC, and may indicate iron-deficiency anemia. Conversely, hyperchromic RBCs have an elevated MCHC because of the presence of greater amounts of Hgb. Hyperchromic cells are not commonly encountered.

Reticulocytes

Adults—Reference Range: 0.5%–1.5% of RBCs or 0.005–0.015

Reticulocytes are young, immature erythrocytes and typically comprise about 1% of the RBCs. The reticulocyte count measures the percentage of these new cells in the circulating blood. An increase in the number of reticulocytes implies an increased number of erythrocytes are being released into the blood in response to a stimulus. Reticulocyte count is a good indicator of bone marrow activity because it represents a recent production. Because erythrocytes regenerate rapidly, reticulocytosis can be noted within 3 to 5 days after hemolysis or after a hemorrhagic episode. Appropriate treatment of anemias caused by iron, vitamin B_{12}, or folic acid deficiencies should result in an increased reticulocyte count. Caution must be exercised in the interpretation of reticulocyte counts. Changes in the number of RBCs will result in proportional changes in the reticulocyte count because the latter is reported as a percentage of the number of RBCs.

Erythrocyte Sedimentation Rate

Reference Range: 0–30 mm/hour

The ESR is the rate (expressed in mm/hour) at which erythrocytes settle to the bottom of a test tube through the forces of gravity and in response to fibrinogen levels in the blood. The ESR is a nonspecific value and may be increased abnormally in acute and chronic inflammatory processes, acute and chronic infections, neoplasms, infarction, tissue necrosis, rheumatoid-collagen disease, dysproteinemias, nephritis, and pregnancy. However, ESR can also be affected by changes not related to the inflammation (e.g., change in erythrocyte size, shape, or number). Laboratory technique can also affect the sedimentation rate substantially. Because many factors can enhance the settling rate of RBCs, moderate to marked elevation of the ESR merely indicates an inflammatory component to a disease state. An increased ESR in the setting of a normal physical examination is usually transient and is rarely the harbinger of serious occult disease.[35]

White Blood Cells

Reference Range: 3.8–9.8 × 10^3/μL or 3.8–9.8 × 10^9/L

Leukocytes or WBCs comprise five different types of cells. Neutrophils are the most abundant of the circulating WBCs, followed in order of frequency by lymphocytes, monocytes, eosinophils, and basophils. The neutrophils, eosinophils, basophils, and monocytes are formed from stem cells in the bone marrow. Lymphocytes are formed primarily in the lymph nodes, thymus, spleen, and, to a lesser extent, bone marrow (Fig. 2-2). Each WBC type has unique function, and it is best to consider them independently rather than collectively as "leukocytes."[36] Ultimately, all WBCs contribute to host defense mechanisms.

NEUTROPHILS

Reference Range: 40%–70% of WBC

The terms polys, segs, polymorphonuclear neutrophils, and granulocytes are synonymous with the term neutrophil in clinical practice. The number of neutrophils is commonly increased during bacterial or fungal infections, because these cells are essential in killing invading microorganisms. Whereas the bone marrow increases production of new leukocytes, there is also an increase in the number of circulating immature neutrophils (e.g., bands); this phenomenon is commonly referred to as a "left shift," which suggests acute bacterial infection.

However, neutrophils are also important in the pathogenesis of tissue damage in some noninfectious diseases, such as rheumatoid arthritis, inflammatory bowel disease, asthma, MI, or gout.[37] Increased neutrophils or neutrophilia can also be encountered during metabolic toxic states (e.g., diabetic ketoacidosis, uremia, and eclampsia) and during physiologic response to stress (e.g., physical exercise and childbirth). Drugs (e.g., epinephrine and corticosteroids) can also cause significant neutrophilia, primarily caused by demargination from blood vessel walls.

Agranulocytosis and Absolute Neutrophil Count

The condition involving decreased neutrophils, or neutropenia, is defined as a neutrophil count of <2,000 cells/μL; agranulocytosis refers to severe neutropenia. The most common causes of neutropenia are metastatic carcinoma, lymphoma, and chemotherapeutic agents. The degree of neutropenia is often expressed by the absolute neutrophil count (ANC). The ANC is defined as the total number of granulocytes (polymorphonuclear leukocytes and band forms) present in the circulating pool of WBCs and can be calculated as WBC × (% neutrophils + % bands)/100. Generally, the risk of infection is low when the ANC exceeds 1,000/ μL; however, the risk of infection increases significantly when the ANC is less than 500/μL. The risk of developing bacteremia is increased further as the ANC decreases to less than 100/μL, a condition commonly referred to as "profound neutropenia." The most common causes of neutropenia are metastatic carcinoma, lymphoma, and chemotherapeutic agents. The reader is referred to Chapter 75, Prevention and Treatment of Infections in Neutropenic Patients, for a more detailed explanation.

LYMPHOCYTES

Reference Range: 22%–44% of WBC

Lymphocytes constitute the second most common WBC in circulating blood. These leukocytes respond to foreign antigens by initiating the immune defense system. The vast majority of lymphocytes are located in the spleen, lymph nodes, and other organized lymphatic tissue. The lymphocytes circulating in blood represent less than 5% of the total amount in the body.

There are two major types of lymphocytes. T lymphocytes (thymic dependent) participate in cell-mediated immune responses, and B lymphocytes (bone marrow derived) are responsible for humoral antibody responses. Therefore, diseases affecting lymphocytes primarily manifest themselves as immune deficiency disorders that render the patient unable to defend against normal pathogens (see Chapter 76, Pharmacotherapy of Human Immunodeficiency Virus Infection) or as autoimmune diseases in which immune responses are directed against the body's own cells.[36]

Increased numbers of lymphocytes on a white count differential sometimes accompany lymphoma (see Chapter 96, Adult Hematologic Malignancies) and viral infections. A relative lymphocytosis is sometimes encountered when the total lymphocytes have remained constant despite a decline in the total neutrophils.

MONOCYTES

Reference Range: 4%–11% of WBC

Monocytes are formed in the bone marrow and are the precursors to macrophages and antigen-presenting cells (dendritic cells), which are found in the body's tissues.[38] Macrophages and dendritic cells are phagocytic cells that engulf foreign antigens or dead or dying cells. Dendritic cells also present fragments of antigens to T and B lymphocytes. Monocytosis may be observed in mononucleosis, subacute bacterial endocarditis, malaria, and tuberculosis, as well as during the recovery phase of some infections.

EOSINOPHILS

Reference Range: 0%–8% of WBC

Because eosinophils have surface receptors that bind IgG and IgE, they can modify reactions associated with IgG- and IgE-mediated degranulation of mast cells. Primary lysosomal granules, small dense granules, and specific or secondary granules are the three types of granules found within eosinophils. The latter granules account for most of the biologic activity of eosinophils and are toxic to parasites, tumor cells, and some epithelial cells.[39]

Eosinophils have phagocytic activity, catalyze the oxidation of many substances, facilitate killing of microorganisms, initiate mast cell secretion, protect against various parasites, and play some role in host defense. Eosinophilia is probably most commonly associated with allergic reactions to drugs, allergic disorders (e.g., hay fever, asthma, and eczema), invasive parasitic infections (e.g., hookworm, schistosomiasis, and trichinosis), collagen vascular diseases (e.g., rheumatoid arthritis, eosinophilic fasciitis, and eosinophilic-myalgia syndrome), and malignancies (e.g., Hodgkin lymphoma).[40–42]

BASOPHILS

Reference Range: 0%–3% of WBC

During infection or inflammation, basophils leave the blood and mobilize as mast cells to the affected site and release granules. These granules contain histamine, serotonin, prostaglandins, and leukotrienes. Degranulation results in an increased blood flow to the site and may compound inflammatory processes. An increase in basophils commonly accompanies allergic and anaphylactic responses, chronic myeloid leukemia, myelofibrosis, and polycythemia vera. A decrease in the number of basophils is generally not readily apparent because of the small number of these cells in the blood.[36]

CASE 2-5

QUESTION 1: L.H., a 50-year-old female, is hospitalized with a sustained high fever of 39.2°C and severe back pain. The results of the CBC and leukocyte differential are as follows:

Total WBC count: 21,000/µL
Neutrophils: 74%
Bands: 6%
Lymphocytes: 14.6%
Monocytes: 8%
Eosinophils: 1%
Basophils: 0%

Imaging and other blood work was ordered. L.H. is diagnosed with an abscess in her lower back and Staphylococcus aureus bacteremia. How is L.H.'s laboratory report consistent with a systemic bacterial infection?

WBCs are the host's chief defense system, and the neutrophil is the main component of that system. During bacterial infections, the leukocyte count and the neutrophils are generally increased, and a left shift (increase in bands) may be noticeable. The percentage of other types of WBCs is decreased proportionately because the number of neutrophils is increased.

As the infection progresses, the percentage of band cells may decrease as a result of an increase in the number of neutrophils that have a longer half-life. This decrease in bands does not necessarily indicate improvement. A decrease in the percentage of neutrophils with a decrease in the total WBC count is characteristic of effective antibiotic therapy.

CASE 2-5, QUESTION 2: The S. aureus causing L.H.'s bacteremia is found to be methicillin sensitive, and she is started on oxacillin 2 million units IV q 4 hour for treatment. After about a week of therapy, L.H. develops a fine red rash all over her body, mild lymphadenopathy, low-grade fever, and generalized swelling. The CBC shows a total WBC count of 8,600/µL with 11% eosinophils. What is the significance of this eosinophil count?

In the clinical setting, absolute leukocyte counts may be used in conjunction with normal reference values. Absolute counts are calculated by multiplying the percentage of each individual cell by the total leukocyte count. Eosinophils are usually increased in allergic reactions; therefore, a drug-induced hypersensitivity reaction is a strong probability in L.H., with an absolute count of 946 eosinophils/μL (i.e., 11% of 8,600 leukocytes). The clinician should be suspicious of an allergic drug reaction when absolute eosinophil counts exceed 300 cells/μL. Eosinophils may increase before, after, or concurrent with other evidence of allergy (e.g., rash). Eosinophilia without evidence of allergy is not sufficient cause to discontinue a suspected medication unless the eosinophilia is significant (i.e., >2,000 cells/μL). In addition, the absence of eosinophilia certainly does not rule out an allergic diagnosis in a patient exhibiting clear clinical manifestations of an apparent allergic reaction.

Thrombocytes

Reference Range: 150–450 × 10^3/μL or 150–450 × 10^9/L

Thrombocytes, commonly referred to as platelets, are tiny fragments of cells that assist with normal blood clotting. Platelet testing is included as part of a CBC and is often ordered along with other coagulation studies to evaluate bleeding and/or clotting disorders. Decreased platelet counts or thrombocytopenia may lead to petechiae, ecchymosis, and spontaneous hemorrhage.

Causes include decreased platelet production, accelerated destruction, loss from excessive bleeding or trauma, dilution of blood samples secondary to blood transfusion, sequestration secondary to hypersplenism, disseminated intravascular coagulation, infection, or systemic lupus erythematosus. Malignancy, rheumatoid arthritis, iron-deficiency anemia, polycythemia vera, and postsplenectomy syndromes are the most common causes of elevated platelet counts or thrombocytosis.

Coagulation Studies

The control of bleeding depends on the formation of a platelet plug and the formation of a stable fibrin clot. The formation of this clot depends on the complex interactions of plasma proteins and clotting factors. The prothrombin time (PT), international normalized ratio (INR), and activated partial thromboplastin time (aPTT) are used to diagnose coagulation abnormalities or to monitor the effectiveness of patients receiving anticoagulation therapy. When used to assess drug therapy, achieving a value outside the reference range is in fact a therapeutically desirable outcome.

ACTIVATED PARTIAL THROMBOPLASTIN TIME

Reference Range: 22–37 seconds

aPTT measures the time it takes the body to form a clot. aPTT depends on the activity of factors VIII, IX, XI, and XII (intrinsic pathway) and the factors involved in the final common pathway of the clotting cascade (II, X, and V). aPTT is commonly measured to detect bleeding disorders and coagulation deficiencies and monitor unfractionated heparin therapy. The reader is referred to Chapter 11, Thrombosis, for more detailed information regarding the use of coagulation parameters in treating and monitoring thrombotic disorders.

PROTHROMBIN TIME

Reference Range: 10–13 seconds

Prothrombin is synthesized in the liver and is converted to thrombin during the blood clotting process. Thrombin formation is the critical event in the hemostatic process because thrombin creates fibrin monomers that ultimately assemble into a clot and stimulates platelet activation. The PT test evaluates the integrity of the extrinsic and common pathways and directly measures the activity of clotting factors VII and X, prothrombin (factor II), and fibrinogen. Automated laboratory instruments measure PT by recording the time required for the blood to clot after a reagent (i.e., tissue thromboplastin) has been added to the patient's blood sample.

INTERNATIONAL NORMALIZED RATIO

Because different labs use different reagents, the PT results obtained from one reagent cannot be reliably compared with another reagent. Therefore, the INR is used as a standard unit to report the result of a PT test. The INR is the recommended method to monitor both the initiation and maintenance of anticoagulant therapy, most notably warfarin. Individuals who have normal blood clotting and are not on anticoagulation therapy should have an INR of 1. For patients on anticoagulation therapy, the target INR (i.e., therapeutic range) is usually between 2.0 and 4.0 depending on the indication and other patient-specific factors. Outside of the therapeutic range, the higher the INR, the higher the likelihood of bleeding because the blood is taking longer to clot. Conversely, if the INR is lower, there is an increased risk of developing a clot. Many factors including medications, diet, alcohol intake, and certain medical conditions can influence the INR.

The INR is calculated using Equation 2-12, where the prothrombin ratio (PTR) is the ratio between the patient's PT and the laboratory's control PT, and the ISI is the international sensitivity index. Commercial manufacturers quantify the ISI for the specific thromboplastin reagent used in each lot and report this information in the product package insert:

$$\text{INR} = \{\text{PT (patient)}/\text{PT (control)}\}^{\text{ISI}} = \text{PTR}^{\text{ISI}} \qquad \text{(Eq. 2-12)}$$

URINALYSIS

A standard urinalysis includes physical, chemical, and microscopic evaluations to assist with diagnosis of various urologic conditions. It begins with simple observation of the color and the gross general appearance of the urine specimen. The urine pH and specific gravity are then recorded. Formed elements in the urine are examined microscopically, and the urine is searched routinely for pathologically significant substances that are normally not present (e.g., glucose, blood, ketones, and bile pigments). Urine specimens should be evaluated quickly after collection to minimize unreliable results. The reader is referred to Chapter 71, Urinary Tract Infections, for a more detailed description of the use of urinalysis in the detection and monitoring of urinary tract infections (UTIs).

Gross Appearance of the Specimen

The concentrated, first-morning urine specimen is usually analyzed to eliminate effects of undue dilution as a result of water intake. The color should be slightly yellow, depending on the degree of dilution, and the appearance should be clear. The appearance of the urine may reveal clouds of crystals, bilirubin, blood, porphyrins, proteins, food or drug colorings, or melanin. Discolored urine is abnormal. A red coloration of the urine may be imparted by blood, porphyria, or ingestion of phenolphthalein. A brown urine color may be caused by the acid hematin of blood or from melanin pigments. Excessive excretion of urobilinogen or the effects of drugs such as rifampin or phenazopyridine may cause a dark orange urine color. A blue to blue-green color of the urine may result from the systemic administration of methylene blue.

Specimen pH

When freshly produced, urinary pH can range from 4.5 to 8 but is mostly acidic because of metabolic activity. Alkaline urine may indicate an aged specimen, systemic alkalosis, failure of renal acidifying mechanisms, or infection in the urinary tract.

Specific Gravity

Urinary specific gravity provides information regarding a patient’s hydration status. A normal morning urine specimen should have a specific gravity of 1.003 to 1.030. The upper end of this range is close to the maximal concentrating ability of the kidney. A value of 1.010 or less supports relative hydration, whereas a value greater than 1.020 indicates relative dehydration.

Protein

Proteinuria is a classic sign of renal injury. If proteinuria is found during the evaluation of a patient with a nonrenal illness, it suggests that the disease may also involve the kidneys (i.e., hypertension and diabetes).[43] A healthy adult generally excretes 30 to 130 mg/day of protein into the urine.

Protein in a urine sample is generally tested qualitatively on a random urine sample by a dipstick method and is usually reported on a scale of 0 (<30 mg/dL), 1+ (30–100 mg/dL), 2+ (100–300 mg/dL), 3+ (300–1,000 mg/dL), and 4+ (>1,000 mg/dL). A positive qualitative test for urine protein should be repeated after a few days because transient proteinuria can accompany various physiologic and pathologic states, even when kidney function is normal. Therefore, patients with CHF, seizures, or febrile illnesses and normal renal function need not undergo invasive renal function tests if the proteinuria is modest and likely to be transient. Another qualitative evaluation of proteinuria can be performed in about 2 weeks to confirm the diagnosis of transient proteinuria.[44] If subsequent qualitative test results are positive, a 24-hour urine sample should be collected to quantitatively test for protein and creatinine (see Creatinine Clearance section). In patients with a normal 24-hour urinary protein concentration, previous positive qualitative test results probably represent either false-positive results or a transient phenomenon.[42] A laboratory parameter being used with increased frequency to assess proteinuria is the urine albumin to urine creatinine ratio (UACR). This measurement tends to be less influenced by fluctuations in urine concentration and may offer a more reliable indication of proteinuria. UACR values are typically less than 30 mg/g; patients with values between 30 and 300 mg/g are considered to have microalbuminuria, and UACR values greater than 300 mg/g indicate macroalbuminemia.

MICROSCOPIC EXAMINATION

The urine sediment is examined for RBCs, WBCs, casts, yeast, crystals, and epithelial cells.

RBCs should be absent in normal urine, although fewer than 4 to 6 RBCs per high-power field (HPF) would still be considered in the normal range. Bleeding or clotting disorders, some collagen diseases, and various bladder, urethral, and prostatic conditions may cause microscopic hematuria. In women, vaginal blood occasionally contaminates the urine specimen, but the presence of numerous squamous epithelial cells should be sufficient to alert clinicians to this artifact.

WBCs should be virtually absent in normal urine, although up to 5 WBCs/HPF would still be in the reference range. The presence of WBCs in the urine (pyuria) usually suggests an acute infection in the urinary tract. Some noninfectious inflammatory diseases of the kidney, ureter, or bladder may also contribute WBCs to the urine sediment.

Casts may be used to identify the location of disease in the genitourinary tract. Casts are composed of proteinaceous or fatty material that outlines the shape of the renal tubules where they are deposited. The presence of casts must be interpreted in light of other factors related to the kidney and its function; however, fatty casts, RBC casts, and WBC casts are always significant. RBC casts usually suggest glomerular injury, and WBC casts suggest tubular or interstitial injury. Lipid casts with proteinuria are characteristic findings in patients with nephrotic syndrome or hypothyroidism.[43] The finding of hyaline casts alone in the presence of proteinuria suggests a renal origin for the protein. Hyaline or granular casts alone, however, only suggest some defect in factors that affect cast formation and are therefore difficult to interpret.

Crystals may originally appear as a cloud in the urine. Their formation is pH dependent, and they often appear only as the urine cools to room temperature or in concentrated urine. In acidic urine, crystals may be uric acid or calcium oxalate; in alkaline urine, they may be phosphates. Crystals per se are not highly significant, although they may reflect a tendency toward the formation of renal calculi.

CASE 2-6

QUESTION 1: S.T. is a 33-year-old female with type 1 diabetes who presents to the urgent care clinic with a 3-day history of fever, malaise, dysuria, and flank pain. Upon interview, you learn that over the past few days, S.T. has been unable to keep down any food because of feelings of nausea. Because of this, she has not taken her insulin for 48 hours. Today, her finger stick blood glucose is 415 mg/dL, and a STAT midstream urinalysis and Gram stain indicate the following:

pH: 5.2
Appearance: cloudy
Specific gravity: 1.033
Urine protein: 3+
Urine glucose: 4+
Urine ketones: positive
Urine bacteria: 4+
Urine WBC: too numerous to count (TNTC)
Squamous epithelial: few per HPF
Urine nitrite: positive
Gram stain: numerous Gram-negative rods

What objective data from the urinalysis indicate a UTI?

The cloudy appearance of S.T.'s urine indicates the presence of bacteria, protein, and WBCs, which is supported by the urinalysis results. The lack of a significant amount of squamous epithelial cells, the presence of a significant amount of nitrite-producing bacteria, and the Gram stain indicate a clean-catch urine specimen and a UTI involving Gram-negative organisms (most likely Escherichia coli that causes a majority of UTIs).

CASE 2-6, QUESTION 2: What objective data from the urinalysis indicate uncontrolled diabetes?

Glucose is normally filtered in the glomerulus and a majority is reabsorbed in the proximal tubule of the kidney. S.T.'s glycosuria (4+ glucose) and fingerstick of 415 mg/dL indicate the filtered amount of glucose exceeds the capacity for reabsorption (˜180 mg/dL). Additionally, the presence of positive ketones indicates the body is utilizing fat, not glucose, for energy. High levels of ketones can predispose S.T. to dehydration, resulting in diabetic ketoacidosis.

THERAPEUTIC DRUG MONITORING

Many drugs have a wide dosing range that can achieve efficacy with low risk of toxicity. Drugs that have a narrow dosing range with high risk of toxicity (narrow therapeutic index) often have their blood levels monitored. Results from therapeutic drug monitoring assist clinicians with appropriate dosing adjustments to prevent toxicity and achieve appropriate clinical outcomes. Pharmacokinetic parameters as well as drug interactions may significantly impact the laboratory results and must be integrated into the clinical assessment of the data. Similarly, for certain drugs and drug classes, there are recommended laboratory tests that should be performed to monitor their potential adverse effects on organ systems. Ideally, blood level monitoring should occur after the drug has reached steady state and at a consistent time within the dosing interval.

PATIENT-DIRECTED MONITORING AND TESTING

Often patient-directed self-monitoring is an essential component to successful management of certain disease states such as blood pressure monitoring for hypertension and blood glucose monitoring for diabetes mellitus. When used appropriately, data obtained from these monitoring devices can be used by health care providers and consumers to initiate or modify therapies accordingly.

Additional laboratory, self-monitoring tests or devices are also available for consumers to purchase for independent testing or screening purposes at home. Some products provide an immediate result, whereas others require submitting a completed kit to a laboratory for analysis. Samples may be obtained from various sources, including urine, blood, saliva, stool, or hair samples. The incidence of consumers using these products has significantly increased and likely will continue to climb because of increased access via the Internet as well as additional tests becoming available.

In the United States, some, but not all, patient-directed tests have been approved by the US Food and Drug Administration (FDA). A current listing of approved products is available through the FDA’s Office of In Vitro Diagnostic Device Evaluation and Safety (OIVD) and can be accessed online at http://www.fda.gov/MedicalDevices/ProductsandMedicalProcedures/InVitroDiag Consumers should be cautioned about the accuracy of tests that have not been approved and the validity of all test results, especially for diagnostic purposes, because many factors can impact or interfere with the sensitivity (probability of obtaining a positive result when sample is truly positive) and specificity (probability of obtaining a negative result when the sample is truly negative). Follow-up assessment with a health care provider should be encouraged to confirm or refute patient-directed test results.

Drug Interactions

Michelle L. Ceresia, Caroline S. Zeind, John Fanikos, and Michael G. Carvalho

CORE PRINCIPLES	CHAPTER CASES
1 A drug interaction is either the result of pharmacokinetic changes of a drug or its metabolites due to alteration in absorption, distribution, metabolism or excretion, or is the result of pharmacodynamic changes, impacting the effect or mechanism of action. There are several types of drug interactions. Whereas the classic interaction involves two drugs (DDI), a drug interaction can involve the interaction of a drug with a nutrient, chemical, food, herbal, disease, or laboratory test.	**Case 3-1 (Questions 2-6), Case 3-2 (Questions 2-3), Case 3-3 (Question 1); Tables 3-1, 3-3, and 3-4**
2 Some patient populations are more vulnerable to drug interactions because of age, gender, race, and comorbidities such as renal and hepatic insufficiency. Drugs that have a higher potential for an interaction are those with a narrow therapeutic index (NTI).	**Case 3-1 (Question 1), Case 3-2 (Question 1), Case 3-3 (Question 1); Table 3-2**
PHARMACOKINETIC CHANGES	
1 Administration/Absorption: Drug interactions resulting from alterations in absorption are caused by (1) changes in gastric pH, (2) formation of complexes in the gastrointestinal (GI) tract, (3) changes in GI motility, and (4) modulation of P-glycoprotein (P-gp) intestinal absorption of drugs.	**Case 3-1 (Question 1), Case 3-2 (Question 3); Table 3-3**
2 Distribution: Drug interactions resulting from displacement of drug bound to protein sites (e.g., albumin), particularly with drugs with a high degree of plasma protein binding that are more likely to be displaced by a drug with greater affinity for the same binding site.	**Case 3-1 (Question 2); Figure 3-1, Table 3-3**
3 Metabolism: A common cause of clinically significant drug interactions during multiple drug therapy involves drug metabolism in which cytochrome P450 isoenzymes (CYPs) play a significant role. Many drug interactions occur as a result of inhibition or induction of CYP enzymes.	**Case 3-1 (Questions 3, 5, 6) Case 3-2 (Question 2), Case 3-3 (Question 1); Figure 3-2, Table 3-3**
4 Excretion/Elimination: Drugs are eliminated mainly through renal tubular excretion and biliary excretion. Drug interactions may occur during the elimination of drugs and their metabolites by the kidney as a result of competition at the level of active tubular secretion, interference with tubular transport, or during tubular reabsorption.	**Case 3-2 (Question 2); Table 3-3**
PHARMACODYNAMICS CHANGES	

①	Pharmacodynamic interactions occur when the presence of one drug changes the effect of another drug without pharmacokinetic alterations. It may be due to competition at the drug receptor level by indirect systems, involving interference with physiologic mechanisms, resulting in additive or synergistic interactions or antagonistic interactions.	**Case 3-1 (Question 4), Case 3-2 (Questions 2, 3); Table 3-4**

RESOURCES AND EVIDENCE FOR CLINICAL DECISION SUPPORT

①	Patient safety initiatives have expanded in efforts to improve the healthcare delivery system with medication error prevention as a high-priority area. Healthcare providers have become increasingly challenged on devising optimal approaches to managing drug interactions. A key challenge is that computerized drug interaction screening systems detect a large number of drug–drug interactions of questionable clinical significance. Expert groups have provided recommendations to improve the usability of clinical decision support alerts for managing drug interactions.	**Case 3-1 (Question 6)**

Because healthcare professionals are committed to ensuring patient safety and preventing drug-related harm, it is important to understand drug interaction principles and how to apply drug interaction decision support tools to provide evidence-based clinical decisions. This chapter will introduce the reader to general principles and concepts of drug interactions. Case studies are incorporated to illustrate the application of key concepts and to highlight the importance of understanding the mechanisms by which drugs interact and how it impacts the clinical assessment and management of drug therapy. Disease-specific chapters within this textbook will also apply drug interaction concepts and incorporate case studies relevant to disease management.

DEFINITION

Drug interactions can be broadly categorized as either pharmacokinetic or pharmacodynamic in nature.[1,2] Pharmacokinetic drug interactions involve absorption, distribution, metabolism, and excretion, whereas pharmacodynamic interactions can be characterized into three subgroups: (1) direct effect at receptor function; (2) interference with a biologic or physiologic control process; and (3) additive or attenuated pharmacologic effect.[3] Another key area of consideration is the biologic variance in a given individual: genetics, age, disease, as well as the internal environmental factors (i.e., the patient's medications, dietary intake, and social habits such as smoking and alcohol consumption).[4]

A drug–drug interaction (DDI) is defined "as a clinically meaningful alteration in the exposure and/or response to a drug (object drug) that has occurred as a result of the coadministration of another drug (precipitant drug)."[1-2,5,6] Drug interactions may have beneficial effects because some drug interactions are used to enhance therapeutic outcomes, whereas other interactions may have deleterious effects that result in serious toxicity or may inhibit the effects of a drug, leading to suboptimal therapeutic outcomes. Whereas the classic interaction involves two drugs (DDI), a drug interaction can involve the interaction of a drug with a nutrient, chemical, food, herbal, disease, or laboratory test.[7,8] A potential drug interaction is defined "as the occurrence in which two drugs that are known to interact are concurrently prescribed, regardless of whether adverse events occurred."[8]

In 2015, consensus recommendations for evaluating drug–drug interactions were published by an expert group that included definitions of relevant terminology for evaluation of DDI evidence.[5] Table 3-1 highlights their recommendations for key terms of relevant terminology for evaluation of DDI evidence (The reader is referred to the complete list of definitions agreed upon by this expert group that are provided in their supplementary publication).[5] They emphasize the importance of consistent use of relevant terminology for evaluation of DDI evidence. For example, a clinically relevant DDI is defined as one that is associated with either toxicity or loss of efficacy that warrants the attention of healthcare professionals.[2]

RISK FACTORS FOR DRUG INTERACTIONS

Some patient populations are more vulnerable to drug interactions because of age, gender, race, and comorbidities such as renal and hepatic insufficiency. Polypharmacy, defined as the concomitant use of multiple drugs or the administration of more medications that are indicated clinically, is a leading cause of DDIs, resulting in higher rates of adverse events, higher drug costs, and medication nonadherence.[9–11] Elderly patients are at an increased risk of drug interactions given the rates of polypharmacy (estimated at 20% to 50%) in the older population, along with multiple comorbidities.[12-14] Adverse drug reactions have been observed 2 to 3 times more frequently in older persons and account for 5% to 17% of all hospital admissions.[15]Age alone is a key risk factor in the elderly population as altered pharmacokinetics and pharmacodynamics may result in a slower intestinal transit time, diminished absorption capacity, decreased liver metabolism and renal excretion, and alterations in volemia and body fat distribution.[16,17] Within the older population, the frail elderly represents a subgroup in which comorbidities primarily account for the observed changes in pharmacokinetic and pharmacodynamic properties.[12] When considering the impact of aging, it is important to differentiate the subgroup of fit elderly from that of the frail elderly, as those who are frail are at increased risk of death, institutionalization, and worsening disability.[12,18,19] A number of studies have shown that females are at greater risk for drug interactions.[20-23] Further research is needed in this area to better understand gender differences with drug interactions.[20-23] The distribution of many drugs may be significantly altered due to marked increases in total body weight (TBW).[24] Drugs that are lipophilic will have an increased volume of distribution. Patients who are obese and those who are malnourished will have altered levels of metabolizing enzymes, increasing their susceptibility to drug interactions.[15,25] Critically ill patients, those with poor nutritional status, and immunocompromised patients are at greater risk of drug interactions. Cigarette smoking can affect drug therapy by both pharmacokinetic and pharmacodynamic mechanisms. It can affect drug therapy by enzyme induction of cytochrome P450; enzymes induced by tobacco smoking may also increase the risk of cancer by enhancing metabolic activation of carcinogens.[26] Drugs that have a higher potential for an interaction are ones with a narrow therapeutic index (NTI) because there are small differences between therapeutic and toxic doses. For example, lithium, a monovalent cation, is a drug with a NTI that is influenced by changes of serum sodium. Patients taking lithium and who are also receiving chronic treatment with thiazides are at risk of lithium toxicity because thiazides can cause a high excretion of sodium that may increase lithium reabsorption.[3]

Table 3-1

Terminology Related to DDI[5]

Terminology	
Drug–drug interaction (DDI)	Clinically meaningful alteration in the exposure and/or response to a drug (object drug) that has occurred as a result of the coadministration of another drug (precipitant drug)
Potential DDI	Coprescription of two drugs known to interact, and therefore, a DDI could occur in the exposed patient
Clinically relevant DDI	Drug–drug interaction associated with either toxicity or loss of efficacy that warrants the attention of healthcare professionals.
Narrow therapeutic index (NTI) drugs	Drugs for which even a small change in drug exposure may lead to toxicity or loss of efficacy

Source: Scheife RT et al. Consensus recommendations for systematic evaluation of drug-drug interaction evidence for clinical decision support. Drug Saf. 2015;38:197–206.

An individual's genetic makeup determines his/her complement of metabolizing enzymes, and based on their genotype, patients may be classified as having a phenotype for ultrarapid metabolizer, extensive metabolizers, intermediate metabolizers, or poor metabolizers (Refer to Chapter 4, Pharmacogenomics and Personalized Medicine).[27] Individuals who use multiple providers and/or multiple pharmacies are more likely to have incomplete information available for both the providers and themselves; this impacts clinical decision-making and increases the likelihood that a drug interaction may go undetected. Individuals who self-prescribe and take over-the-counter (OTC) products (including dietary supplements, vitamins, minerals, and herbal agents) may not understand the potential risk for drug interactions. In addition, if they do not maintain a complete listing of OTC products for themselves and their providers, there is a greater likelihood for adverse drug reactions and drug interactions. Whereas disease-specific chapters in this textbook will provide a wide array of risk factors for drug interactions, Table 3-2 outlines examples of risk factors for drug interactions.

Table 3-2

Risk Factors for Drug Interactions[1,12–33]

Category	Risk Factor	Potential Effect
Patient characteristics Demographics	Age (< 5 years and ≥ 65 years)	Alterations in drug distribution; ↓ clearance which may result in drug accumulation
	Female gender	↓ ability to metabolize compared to males
Social factors	Nutrition	Affects cytochrome p450 activity (e.g., grapefruit juice inhibits CYP 3A4 activity)
	Smoking	Affects cytochrome p450 activity (i.e., induces CYP 1A2)
	Alcohol	Affects cytochrome p450 activity specifically CYP 2E1
Organ dysfunction	↓ renal function	↓ clearance, which may result in ↑ serum concentrations of drug and accumulation
	↓ hepatic function	↓ metabolism, which may result in ↑ serum concentrations and accumulation of the parent drug and/or metabolite
	Heart Failure (HF)	↑ risk due to number of medications prescribed with comorbidities
	Chronic obstructive pulmonary disease (COPD)	↑ risk due to number of medications prescribed with comorbidities
Metabolic and endocrine	Obesity	↑ distribution of lipophilic drugs
	Fatty liver	Altered metabolism
	Hypoproteinemia	↑ serum drug concentration
Genetic[a]	Genetic polymorphisms (ultrarapid, extensive, intermediate, or poor metabolizers)	Altered metabolism
Acute medical conditions	Dehydration	↑ serum drug concentrations
	Hypotension	↓ clearance
	Hypothermia	↓ clearance
	Infection	↑ catabolism

Drug characteristics	Narrow therapeutic index (NTI)	↑ risk of dose-related adverse drug events
	Highly protein bound	↑ free fraction (active drug) from protein displacement
	Small volume of distribution	Drug confined to the plasma
	Cytochrome p450 substrate	↓↑ serum drug concentration with coadministration inducer or inhibitor precipitant drug
	P-glycoprotein substrate	↓↑ serum drug concentration with coadministration inducer or inhibitor precipitant drug
Other factors	Polypharmacy	Risk of adverse drug interactions ↑ with increase in number of medicines
	Number of prescribers	Number of prescribed drugs ↑ with multiple prescribers
	Number of pharmacies utilized	Number of prescribed drugs ↑ with multiple pharmacies; Pharmacist may not have knowledge of all drugs prescribed to patient
	Self-prescribing	OTC medicines interacting with prescribed medicines
	Duration of hospital stay	Susceptible to hospital-acquired conditions and subsequent drug therapy

[a] Refer to Chapter 4 Pharmacogenomics and Personalized Medicine for further information.

CASE 3-1

QUESTION 1: N.M. is a 68-year-old obese, Hispanic female who underwent a total knee replacement at a local teaching hospital. The medical team plans to start N.M. on warfarin therapy for venous thromboembolism prophylaxis with an international normalized ratio (INR) target range of 1.8 to 2.3 for a total duration of 3 weeks. The first dose will be administered in the evening on the day of surgery.

Her medical history includes epilepsy for the past 10 years, controlled with phenytoin; hypercholesterolemia for the past 15 years, for which she takes pravastatin; and hypertension for the past 20 years, for which she takes lisinopril. Her social history includes a 1-pack-year history of smoking. She does not drink alcohol. She takes acetaminophen for headaches and has taken other over-the-counter medicines as needed, but doesn't recall the names of the products. Her renal and hepatic functions are within normal range.

Describe N.M.'s risk factors for drug interactions with the addition of warfarin postsurgery.

N.M. has multiple factors including patient-specific and drug-specific ones that increase her risk for drug interactions. Her patient risk factors include obesity, age, gender, and smoking history.

Patient Risk Factors

- Female gender
- Metabolic: obesity—increased distribution of lipophilic drugs (phenytoin);

comorbidities: hypertension; and hypercholesterolemia
- Age: 66 years old—altered pharmacokinetics and pharmacodynamics
- Smoking history—induces the cytochrome (CYP) P450 system

With regard to drug-specific factors, N.M. has been taking phenytoin, a drug with a NTI, for the past 10 years. She will be receiving warfarin, another agent with NTI. Both medications are metabolized via cytochrome P450 system. In addition, N.M. is at increased risk of additional drug interactions due to polypharmacy because she has chronic disease comorbidities (i.e., seizure disorder, hypertension, and hypercholesterolemia).

Drug Risk Factors

- Warfarin—NTI, highly protein bound to albumin, small volume of distribution, metabolized by cytochrome P450 system
- Phenytoin—NTI, highly protein bound to albumin, metabolized by CYP2C9 and CYP2C19 isoforms, and susceptible to drugs that inhibit hepatic microsomal enzymes
- Pravastatin—whereas pravastatin does not appear to interact with warfarin, other agents in this class (i.e., atorvastatin, fluvastatin, rosuvastatin and simvastatin) have been suspected or are known to alter the INR in patients who receive warfarin[34,35,36]
- Lisinopril—a concern when administered concomitantly with diuretics or potassiu supplementation

Other Risk Factors

- Polypharmacy—prior to admission, she is already on 3 prescription drugs and als takes OTC products. She is a poor historian.

Mechanisms of Drug Interactions

Pharmacokinetics

ADMINISTRATION/ABSORPTION

Following oral administration, most drug absorption occurs in the proximal small intestine.[37] However, drug interactions that alter absorption may occur throughout the gastrointestinal (GI) tract by a variety of different mechanisms, including complexation (adsorption or chelation), changes in pH, changes in GI motility, altered drug transport, and enzymatic metabolism. The net effect of one or more of these mechanisms is a change in the rate of absorption, the extent of absorption, or a combination of both. While interactions that result in a reduced rate of absorption are generally not clinically significant for drugs given over the long term in multiple doses, for acutely administered drugs, such as analgesics or hypnotics, this can lead to an unaccepted delay or therapeutic failure.[1,38]

With regard to changes in gastric pH, the majority of drugs orally administered must be dissolved and absorbed in a gastric pH between 2.5 and 3. Drugs, such as antacids, proton pump inhibitors (PPIs), or H2-antagonists, can alter the kinetics of coadministered drugs.[3] Antifungal agents, such as ketoconazole or itraconazole, require an acidic environment to be properly dissolved. Coadministration with drugs that increase gastric pH may cause a reduction in the dissolution and absorption of antifungal drugs. It is recommended that these antifungal agents be administered at least 2 hours after the administration of antacids.

Coadministration of medications around the same time can result in drug interactions that may be clinically significant. Some antibiotics, such as tetracyclines, will combine with metal ions (e.g., calcium, magnesium, aluminum, iron) to form complexes that are poorly absorbed. Antacids also reduce the absorption of fluoroquinolones (e.g., ciprofloxacin) and tetracyclines because the metal ions form complexes with the drug. Therefore, the antacids and fluoroquinolones should be administered at least 2 hours apart. These types of interactions can decrease clinical effectiveness of the antibiotic and can lead to the emergence of resistant organisms.[33] Drugs that are able to increase the gastric transit, such as metoclopramide due to its prokinetic properties, may accelerate gastric emptying, resulting in decreased absorption of drugs such as digoxin or theophylline.

Altered Drug Transport

Transport proteins, which are present in the intestinal mucosa, are important considerations in clinically relevant DDIs.[37] Some proteins are involved in the transport of compounds from the lumen of the intestine into the portal bloodstream, whereas others are involved in the efflux of compounds from the intestinal mucosa back into the gut lumen. The efflux transporters, particularly a specific glycoprotein, which resides in the cell membrane, P-glycoprotein (P-gp), are the most well known. P-gp is an ATP-dependent transporter that is genetically encoded and located on the apical surface of mucosal cells in the intestine, generally in increasing concentration from the stomach to the colon. In addition, P-gp is also present on a number of lymphocyte subsets and within the brain capillary endothelial cells. The primary role of P-gp is to limit systematic drug exposure, pumping compounds from the inside of the cell back into the gut lumen, into renal tubules in the kidney, and into bile in the liver. Given its presence in various anatomic locations, drug-induced modulation of P-gp activity may affect the absorption and/or distribution of a coadministered substrate medication. There are several drugs that are known to block the action of P-gp and are known as P-gp inhibitors, and there are drugs that have been shown to cause induction of P-gp. Coadministration of a P-gp substrate with an inhibitor increases the amount of substrate available for absorption and may result in an elevated serum drug concentration. For drugs such as rifampin that increase expression of P-gp (i.e., P-gp inducer), the coadministration of a substrate results in an enhanced efflux of the substrate into the gut lumen and lowers serum concentration of the substrate.

DISTRIBUTION

CASE 3-1, QUESTION 2: Describe the interaction of warfarin and phenytoin based on protein binding.

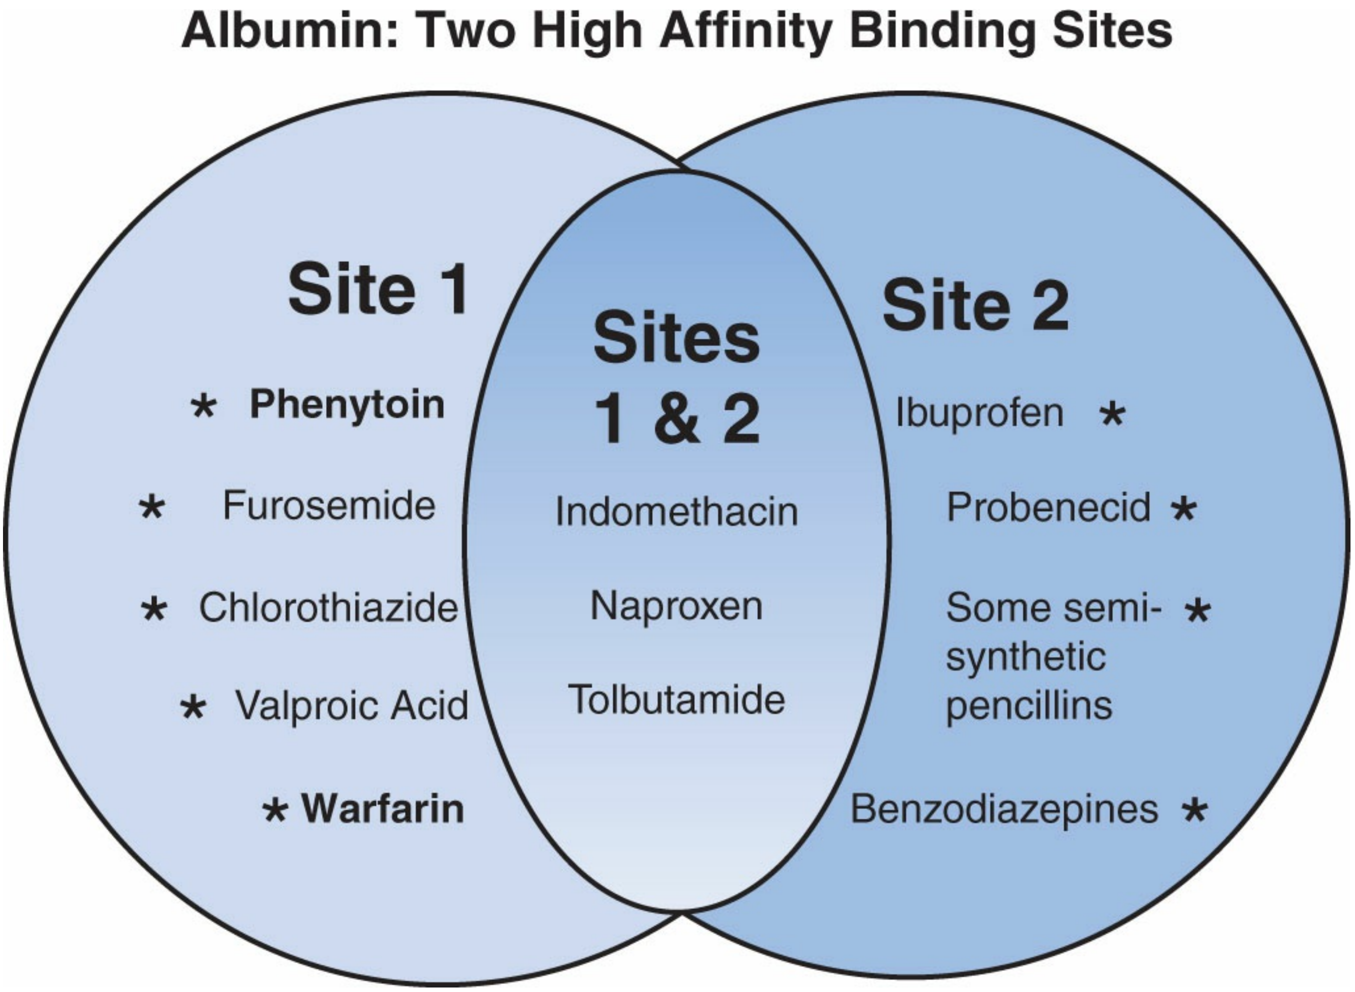
Following administration and absorption, drugs are distributed throughout the body.[37,38] While some drugs have near-complete dissolution in the plasma, drugs such as warfarin and phenytoin are highly bound to protein (primarily to albumin) with the same affinity binding sites (Figure 3-1). Drugs that are highly protein bound (>90%), those with a NTI, and those with a small volume of distribution are more likely to result in significant drug interactions.

Warfarin can be displaced from protein-binding sites by drugs such as phenytoin. Although this displacement occurs quickly with rapid changes in serum warfarin levels, typically this interaction is not clinically significant. Warfarin that is displaced from protein-binding sites is readily available for elimination by hepatic metabolism, resulting in increased clearance without a significant change in the free drug concentration. Because warfarin's anticoagulant action takes several days due to the long half-lives of some of the vitamin K-dependent clotting factors, warfarin equilibrium is re-established before a new steady state can be reached for these clotting factors.[32]

METABOLISM

Pharmacokinetic interactions that involve changes in metabolism are a common cause of clinically significant drug interactions. Drug metabolism is divided into two general categories: phase I and phase II reactions.[37,38] Phase I reactions involve intramolecular changes including oxidation, reduction, and hydrolysis, which increases the polar nature of the drug, generally making it less toxic. Phase II reactions generally involve combining a phase I product with an endogenous substance resulting in glucuronidation, sulfation, acetylation, and methylation, and primarily results in termination of biologic activity of the drug.[39,40] The main enzymes that are responsible for drug-metabolizing systems in phase I reactions are the cytochrome (CYP) 450 enzymes, which play a key role in many therapeutically important drug interactions.[1,2] Drugs that are metabolized by the same CYP450 enzyme family, when administered concurrently, may interact with each other as a result of induction or inhibition.[39,40] Of the human CYP450 enzyme family, the 6 isozymes CYP1A2, CYP2C9, CYP2C19, CYP2D6, CYP3A4, and CYP3A5 contribute to the metabolism of a vast majority of drugs compared with other enzymes (Figure 3-2).[6,41-43] Examples of drug that induce enzymes are rifampin, phenytoin, carbamazepine, St. John's-wort, and nevirapine. Enzyme inducers cause an increase in the synthesis of the enzyme(s) responsible for metabolism of the substrate drug. The mechanisms of induction are complex involving presystemic metabolism via induction of hepatic and/or intestinal drug-metabolizing enzymes, subsequently reducing serum concentrations with a loss of pharmacologic activity of the drug. In some cases, induction will increase the formation of metabolites that are pharmacologically or toxicologically active.[1,43,44] There are many drugs that are inhibitors of CYP450 including some drugs within these classes: statins, macrolide antibiotics, antifungal azoles, fluoroquinolones, and HIV protease inhibitors. Inhibition of drug metabolism slows down the rate of drug metabolism, resulting in an increase in the amount of drug in the body and potential toxicity. Grapefruit juice is an inhibitor of CYP3A4 and has been known to increase the bioavailability and reduce the clearance of many drugs including HMG-CoA reductase inhibitors (statins), calcium antagonists, HIV protease inhibitors, and immunosuppressant agents.[45-48] Inhibition can be described as reversible or irreversible, with the reversible ones being a more common process. There are three mechanisms of reversible inhibition: competitive inhibition (competition between the inhibitor and the substrate for the enzyme's active site); noncompetitive inhibition (binding of the inhibitor to a separate site on the enzyme, rendering the enzyme complex nonfunctional); or uncompetitive inhibition (binding of the inhibitor only to the substrate–enzyme complex, rendering it ineffective).[1,48,49] Irreversible inhibition occurs when the perpetrator drug forms a reactive intermediate with the enzyme that leads to a permanent inhibition of the enzyme. Irreversible drug interactions tend to be more profound than those caused by reversible mechanisms. Examples of drugs that are known to cause irreversible inhibition include macrolide antibiotics, erythromycin, clarithromycin, paroxetine, and diltiazem.[15,50,51]

CASE 3-1, QUESTION 3: The medical team starts N.M. on warfarin therapy postsurgery for thromboembolism prophylaxis. The medical intern asks you to explain the mechanisms of drug interactions to consider with the use of warfarin and phenytoin because N.M has been on phenytoin for the past 10 years and her seizure disorder has been controlled on it.



Albumin: Two High Affinity Binding Sites
Site 1
★ Phenytoin
★ Furosemide
★ Chlorothiazide
★ Valproic Acid
★ Warfarin
Sites 1 & 2
Indomethacin
Naproxen
Tolbutamide
Site 2
Ibuprofen ★
Probenecid ★

Benzodiazepines ★

Figure 3-1 Examples of drugs that bind to and compete for one of two sites, designation I and II, on albumin. (Adapted from Drug Interactions. In: Rowland M et al, eds. Clinical Pharmacokinetics and Pharmacodynamics: Concepts and Applications. 4th ed. Baltimore, MD: Lippincott Williams & Wilkins; 2011:490.)

There are two potential mechanisms for a warfarin (drug)–phenytoin (drug) interaction. In early therapy, there could be a displacement of warfarin from protein-binding sites by phenytoin (as described in the previous case question), and a possible enhancement of the anticoagulant effect and risk for bleeding. This is primarily a concern in patients with hepatic impairment. With prolonged therapy, there could be a phenytoin-induced, CYP enzyme induction thereby enhancing warfarin metabolism resulting in a decreased warfarin effect. INR monitoring on postoperative days 1 through 5 will provide information on the impact of the DDI and incorporation of a warfarin initiation guideline or algorithm will help adjust dosing until a stable regimen is established. After the initial period, weekly INR monitoring will provide information on enzyme induction and further adjustment of warfarin doses.

Figure 3-2 Graphic representation of the different forms of cytochrome-P450 (circles) in humans with different but some overlapping substrate specificities. The arrows indicate single metabolic pathways. Representative substrates are listed above for each enzyme. Also listed are relatively selective inhibitors and inducers of the enzymes. (Reprinted from Drug Interactions. In: Rowland M, Tozer TN, eds. Clinical Pharmacokinetics and Pharmacodynamics: Concepts and Applications. 4th ed. Baltimore, MD: Lippincott Williams & Wilkins; 2011, with permission.)

Warfarin is rapidly and completely absorbed after oral administration with the proximal duodenum appearing to be the most likely location of absorption. Case reports of warfarin malabsorption, whether acquired, related to surgery, or inflammatory conditions, are rare.[52]

The rate and extent of phenytoin absorption varies considerably among oral dosage forms.[53] Phenytoin suspension is poorly absorbed when administered via feeding tube with continuous enteral feedings.[54] The time to reach maximum plasma levels increases with increasing dose.[55] This is a reflection of low phenytoin solubility and capacity-limited metabolism. Therefore, a small change in the dosage form or bioavailability, coupled with limited metabolism, can produce a large change in plasma drug concentration.[56] GI surgery and GI inflammatory conditions (Crohn's disease, ulcerative colitis, scleroderma, etc.) can change the anatomy of the GI tract.

Alterations to surface area, gastric emptying time, gastric pH, and inflammation of the intestinal lining may lead to abnormal plasma concentrations.[57]

N.M.'s GI function is still preserved after orthopedic surgery. Warfarin administration and absorption is unlikely to be impacted. She should continue on the same phenytoin dose and formulation that she has been taking at home with appropriate monitoring.

Pharmacokinetic interactions influencing the metabolism of warfarin and clinically significant interactions are likely with warfarin use when its metabolism is induced or inhibited.[48] Warfarin is a racemic mixture of R- and S-enantiomers. Interactions involving agents known to influence the hepatic microsomal enzyme systems responsible for the metabolism of the more potent S-enantiomer (CYP2C9) are more significant than those that influence the enzymes that metabolize R-enantiomer (CYP1A2, CYP3A4). Phenytoin is also predominately metabolized via the CYP2C9 enzyme and has been reported to interact with warfarin in a biphasic manner.[49-51]

Genetic polymorphism also is a significant factor affecting warfarin dosing and response. Nucleotide polymorphisms have been identified that influence warfarin metabolism and sensitivity, including variants of CYP2C9 and variants in vitamin K epoxide reductase complex (VKORC1).[58]

EXCRETION/ELIMINATION

Drugs are excreted and eliminated mainly via the kidneys (glomerular filtration, tubular reabsorption, and active tubular secretion); other important, though less common, routes are via biliary secretion, plasma esterases, and other minor pathways. Drug interactions may occur during the elimination of drugs and their metabolites by the kidney as a result of competition at the level of active tubular secretion, interference with tubular transport, or during tubular reabsorption.

Urinary alkalinization and acidification by some drugs can affect the excretion of other drugs changing their elimination rate. For example, the use of probenecid, a potent inhibitor of the anionic pathway of renal tubular secretion, increases the serum concentration of penicillins, which can be used for therapeutic purposes.

Pharmacodynamics

Pharmacodynamic interactions occur when the response of one drug is modified by the presence of another one without alterations in pharmacokinetics. These types of interactions may

be predicted if the pharmacologic effects of a drug are known, and the patient response may be additive or antagonistic.[2,8] For example, there may be an interaction in which one drug, an ACE inhibitor, and another drug, a thiazide diuretic, each act by a different mechanism of action to lower blood pressure, producing an exaggerated hypotensive effect.

CASE 3-1, QUESTION 4: The intern asks you to explain the pharmacodynamic interactions that are clinically relevant to warfarin.

Pharmacodynamic interactions with warfarin are those that alter the physiology of hemostasis, particularly interactions that influence the synthesis or degradation of clotting factors or that increase the risk of bleeding through inhibition of platelet aggregation. In patients receiving warfarin, the addition of any drugs that increase or decrease clotting factor synthesis, enhance or reduce clotting factor catabolism, or that impair vitamin K production by normal flora will increase the risk of drug interactions.

Tables 3-3 and 3-4 provide examples of common mechanisms of pharmacokinetic and pharmacodynamic drug interactions, respectively.

MANAGEMENT OF DRUG INTERACTIONS

CASE 3-1, QUESTION 5: The medical intern on the team also plans to prescribe a combination analgesic (oxycodone/acetaminophen) in place of intravenous morphine for the pain management.

In a telephone conversation, N.M. expressed to a friend that she felt depressed. As a result, her friend brought her a bottle of St. John's-wort.

As the pharmacist on the multidisciplinary team your role is to assess therapy and make recommendations as needed. Provide appropriate recommendations regarding N.M.'s therapy, including the use of St. John's-wort.

Although acetaminophen is a commonly used nonprescription analgesic and antipyretic medication for mild-to-moderate pain and fever, its presence is often unrecognized in combination products containing opioids prescribed for moderate-to-severe pain. Several studies have identified acetaminophen as a culprit drug in potentiating the effects of warfarin.[66] Patients who take four 325-mg acetaminophen tablets per day for longer than a week were more likely to have an INR above 6.0 than those who did not take acetaminophen.

There is no evidence for a pharmacokinetic interaction between acetaminophen and warfarin.[67] However, acetaminophen is metabolized by CYP2E1 producing the metabolite N-acetyl-p-benzoquinone-imine (NAPQ1). NAPQ1 oxidizes vitamin K-hydroquinone (KH2), the "active" form of vitamin K, and directly inhibits vitamin K-dependent carboxylation. There may be other oxidative changes, producing enzymatic disruption, that impact vitamin k synthesis and activity. The end result is an exaggerated response to warfarin and an increased INR.

Therefore if N.M. is to be placed on oxycodone/acetaminophen therapy, her INR should be monitored more frequently and her dose adjusted accordingly. This is important particularly if she requires higher sustained doses of warfarin.

Dietary supplements, including herbal medicinals, amino acids, and other nonprescription products, are not tested before marketing for interactions with other medications, including warfarin. Little is known about their interactive properties, other than published case reports of varying quality. In addition, dietary supplements are not required to meet US Pharmacopeia standards for tablet content uniformity.

St. John's-wort, an herb whose yellow flowers and leaves are used to make herbal supplements, has been used for treatment of depression. It has also been shown to lower patient INR values and potentially decrease warfarin's effectiveness.[68,69] Although this interaction is probably due to the induction of CYP2C9, the degree of induction is unpredictable due to variable quality and quantity of the herbal constituent in the preparations. Similarly, St. John's-wort has been suspected of reducing phenytoin plasma concentrations through induction of CYP3A4.

The addition of St. John's-wort to N.M.'s current drug regimen would not be advisable because it would increase her risk for drug interactions. The implications for initiating St. John's-wort in N.M. would require measurement of phenytoin and more frequent INR testing to ensure a new steady state for each agent has been reached. At this point, it is important to assess N.M.'s depression and to evaluate therapeutic options that would provide the least risk of drug interactions, as well as psychosocial treatment.

CASE 3-1, QUESTION 6: Pravastatin, the medication that N.M. was taking prior to admission, is not available on the hospital's formulary list. Therefore, the medical intern prescribes the formulary-preferred agent rosuvastatin postsurgery. He receives an electronic health record drug interaction alert regarding the statin and warfarin and asks you how this should be managed.

Rosuvastatin is not metabolized extensively by the CYP 450 system (approximately 10% with CYP2C9 and CYP2C19 being the primary isoenzymes involved). However, the combination of rosuvastatin and warfarin has resulted in an increase in the INR and hence increasing risk of bleeding.[34-36] Each of the statin agents is metabolized by different CYP isoenzymes and to different degrees (Table 3-5). The goal of lipid management is to prescribe an agent with the least side effects and at the lowest effective dose. If a patient, such as N.M., requires a drug that interacts with statin metabolism (CYP), switching to a statin that has a more favorable elimination profile may be the best option. In this instance, pravastatin, which has limited CYP metabolism and is primarily excreted unchanged in the urine, may be the optimal choice. Otherwise, rosuvastatin may be used but more frequent monitoring of the INR is recommended until a stable INR has been reached. Table 3-5 provides a summary of the metabolism of HMG-CoA reductase inhibitors. Refer to Chapter 8 Dyslipidemias, Atherosclerosis, and Coronary Heart Disease for more information on the use of statins, including drug interactions.

CASE 3-2

QUESTION 1: J.A. is a 69-year-old previously healthy male who was admitted to the medical intensive care unit (ICU) with lower left lobe pneumonia, and he has developed septic shock. His hospital course for the first

18 days of admission consisted of a worsening bilateral pneumonia characterized by profound hypoxia and acute respiratory distress syndrome (ARDS). J.A. is currently deeply sedated and receiving neuromuscular blockade to manage his ARDS, high peak inspiratory pressures (PIPs), and low oxygen saturation (Sao_2).

Medications:

- Propofol IV infusion and fentanyl IV infusion for sedation and analgesia
- Cisatracurium IV infusion for neuromuscular blockade—goal is to improve oxygenation (PaO_2/ FiO_2 ratio)
- Pantoprazole IV for stress ulcer prophylaxis
- Heparin SC and pneumatic compression boots for Deep Venous thrombosis (DVT) prophylaxis
- Hydrocortisone IV for corticosteroid insufficiency in critical illness
- Amikacin IV and imipenem/cilastatin IV for day 5 treatment of a multidrug resistant organism
- Norepinephrine and vasopressin IV infusions for septic shock secondary to pneumonia
- Ophthalmic ointment to lubricate eye while on prolonged neuromuscular blockade
- Lactated Ringer’s IV infusion for hypotension secondary to septic shock

Vitals: T 101°F HR 105 RR 20 BP 95/60

Laboratory values: ABG: pH 7.30 /pCO_2 42/pO_2 80/CO_2 19/Sao_2 90% on mechanical ventilation: Assist control RR 20 tidal volume 400 mL PEEP 10 FiO_2 50%

Serum phosphate	0.9 mg/dL	ALT	85 U/mL

J.A.’s train-of-four (TOF) is 0/4. A peripheral nerve stimulator, the TOF, is a clinical tool used to monitor neuromuscular blockade. The TOF Scale includes the following: 0/4 indicates that no twitch elicited, neuromuscular blocker agent occupies 100% of postsynaptic nicotinic receptors, and a 100% blockade whereas 4/4 indicates that <75% of the postsynaptic nicotinic receptors are blocked. The goal of neuromuscular therapy is to achieve an adequate neuromuscular blockade, a TOF of 1/4 or 2/4 (80% to 90% of receptors blocked) or the desired clinical effect (e.g., accepting ventilation and not over breathing the ventilator), with the lowest dose of neuromuscular agent necessary.[71,72]

Describe J.A.’s risk factors for drug interactions.

Table 3-3

Common Mechanisms of Pharmacokinetic Drug Interactions[1,3,6,16,31–33,37,59–64]

	Mechanism	Example
Pharmacokinetics: administration/absorption	Drugs that alter the pH of the stomach can affect	Itraconazole requires an acidic gastric pH to become soluble; absorption may be decreased if a patient is taking

	absorption of other drugs	a drug that increases gastric pH such as a PPI or H_2-blocker
	Induction or inhibition of CYP enzymes in the gastrointestinal (GI) tract	Grapefruit juice inhibits intestinal CYP 3A4 potentially increasing the bioavailability of CYP 3A4 substrates such as nifedipine and verapamil
	Induction or inhibition of P-gp (an efflux pump that expels drugs) in GI tract	Dabigatran, a substrate for P-gp, peak concentrations may be increased by P-gp inhibitors (e.g., ketoconazole, clarithromycin, amiodarone) leading to a significantly increased risk of bleeding
	Increase or delay gastric emptying/motility	Erythromycin, a potent prokinetic agent, is a motilin receptor agonist that increases gastric motility; absorption of coadministered drugs may be affected
	Killing enteric bacteria	Antibiotics can kill bacteria that produce deconjugating enzymes; drugs that undergo enterohepatic circulation such as birth control pills may have decreased blood concentrations and half-life because of increased excretion in the feces
	Chelation	Cations such as aluminum or magnesium antacids decrease the GI absorption of tetracycline antibiotics by forming drug–metal complexes
	Physiochemical inactivation	Mixing a furosemide solution with an acidic solution (i.e., with midazolam) decreases the pH sufficiently to cause furosemide precipitation and reduced availability when administered intravenously
Pharmacokinetics: distribution	Interaction between two highly protein-bound drugs (e.g., a precipitant drug has stronger affinity for the same protein-binding site)	Sulfamethoxazole displaces warfarin from protein-binding sites increasing the free fraction. Sulfamethoxazole also inhibits the metabolism of warfarin. As a result, the body cannot compensate to increase the elimination of the high free (active) fraction of warfarin. The end result is likely an increase in the INR and potential risk for bleeding. See chapter 11 for detailed warfarin–sulfamethoxazole drug interaction
	Inhibition of carrier proteins such as P-gp located in blood–brain barrier and organic transporting peptides (OATPs) located in the liver	Cyclosporine may inhibit the transporter OATP1B1 decreasing the hepatic uptake of most statins; efficacy of the statin may be lost because the site of action is located in the liver
Pharmacokinetics: metabolism	Induction or inhibition of CYP enzymes in the liver	Example 1: Fluoroquinolones inhibit metabolism of theophylline via CYP 1A2 enzyme; the extent of the interaction varies between the different fluoroquinolones Example 2: Rifampin has a half-life of 4 hours; however, time to steady state induction with propranolol does not occur until 10–14 days
Pharmacokinetics: excretion/elimination	Administration of two drugs that use the same transport system and undergo active tubular secretion by the kidneys	Methotrexate clearance may be reduced in the presence of salicylates. Salicylates decrease renal perfusion via PGE_2, having the potential to cause renal impairment and competitively inhibit the tubular secretion of methotrexate
	Increased or decreased	Example 1: Quinidine reabsorption may be increased in

	renal tubular absorption	alkalinized urine. Example 2: Thiazide diuretics initially cause sodium excretion followed by compensatory sodium reabsorption. Administered with lithium, a cation can cause increased lithium reabsorption and possible toxic concentrations

Table 3-4

Common Mechanisms of Pharmacodynamic Drug Interactions[65]

	Mechanism	Example
Pharmacodynamics	Additive—two or more medications with comparable pharmacodynamic effects result in an exaggerated and/or toxic response	Administration of thiopental and midazolam during induction. Midazolam reduces the amount of thiopental required for anesthesia
	Antagonistic—the effects of one drug oppose the actions of another drug	Example 1: Antagonism at the same receptor site: reversal of benzodiazepines with flumazenil. Example 2: Opposing pharmacodynamics actions: glucocorticoids cause hyperglycemia opposing the effects of hypoglycemic medications

There are several risk factors for drug interactions in critically ill patients. Critically ill patients are susceptible to drug interactions as a result of a debilitated condition and/or disease state (e.g., changes in physiologic pH and body temperature, electrolyte imbalances, organ failure, etc.), as well as the multitude of medications prescribed as treatment. ICU patients also have altered pharmacokinetics, placing them at an increased risk for an interaction. These changes include the following:

- Decreased GI absorption of enterally administered medications due to the following: hypoperfusion from shock; increased stomach pH from PPI and histamine blocker therapy; decreased GI motility; drug effect on carrier proteins, for example, P-gp;
- Decreased subcutaneous absorption due to the following: edema; vasopressor therapy; and disease-induced peripheral vasoconstriction;
- Increased volume of distribution (V_d) for hydrophilic medications due to increase total body water from fluid resuscitation and third spacing;
- Altered free drug fraction due to increased α-acid glycoprotein from systemic inflammation and decreased albumin plasma concentrations; and
- Half-life ($t_{1/2}$) and Clearance (CL) may be affected from decreased hepatic blood flow, renal or hepatic insufficiency, and induction or inhibition of hepatic enzymes by drugs. Patients without renal insufficiency may exhibit augmented

clearance.[73,74]

Table 3-5

Metabolism of HMG-CoA Reductase Inhibitors (Statins)

Statins[a]	Isoenzyme	Comments
Lovastatin	CYP3A4 substrate	Caution drugs that significantly inhibit its metabolism (potent CYP 3A4 inhibitors)
Simvastatin	CYP3A4 substrate	Caution drugs that significantly inhibit its metabolism (potent CYP 3A4 inhibitors)
Atorvastatin	CYP3A4 substrate	Metabolized by CYP 3A4 but less than lovastatin and simvastatin
Fluvastatin	CYP2C9 substrate	Metabolized primarily by CYP2C9 and to a lesser extent by CYP3A4 and CYP2D6
Pravastatin	Excreted primarily unchanged in urine	Not significantly metabolized by cytochrome P450 system
Rosuvastatin	2C9/2C19	Not extensively metabolized by cytochrome P450 system

[a] Substrates for Pgp → drugs that inhibit Pgp may ↑ statin levels (e.g., cyclosporine, diltiazem).

Adapted from Pharmacist's Letter/Prescriber's Letter, "Clinically Significant Statin Drug Interactions," August 2009, Volume 25, Number 250812 and Pharmacist's Letter/Prescriber's Letter, "Characteristics of the Various Statins," June 2010, Volume 26, Number 260611.[70]

The mode of mechanical ventilation that is used most commonly today is positive pressure ventilation, whereby air is forced into the lungs to improve gas exchange. The use of mechanical ventilation may also affect drug pharmacokinetics by decreasing cardiac output secondary to reduced preload, which in turn may compromise perfusion to the liver and kidneys as well as GFR and urine output.[75] This effect is most pronounced in patients who are hypovolemic. These hemodynamic changes can result in a decrease of the clearance of several drugs.

J.A. has several risk factors for drug interactions. Many of his risk factors are patient-specific, including J.A.'s age, organ dysfunction, and acute medical conditions. Additional risk factors are the extended hospital stay in the ICU and multiple medications. J.A.'s specific risk factors are outlined below.

Patient Risk Factors

- Age: 69 years old—altered pharmacokinetic and pharmacodynamics
- Renal dysfunction: baseline SCr 1.0 mg/dL and current SCr 1.8 mg/dL—decrease renal clearance
- Mild hepatic dysfunction: AST 105 U/mL and ALT 85 U/mL—decreased metabolism
- Pneumonia: T 101°F, WBC 14.6 × 10^3µ/L, poly 80%, bands 12%—increased catabolism

- Hypotension (result of shock): BP 95/60 on norepinephrine, vasopressin, and lactated Ringer's solution—decreased clearance
- Hyperthermia: T 101°F—increased clearance
- Hypophosphatemia: phosphate 0.9 mg/dL—increased neuromuscular blockade (se discussion Case 3-2 Question 2)

- Norepinephrine and vasopressin infusions: potential for decreased blood delivery to liver and kidneys
- Mechanical ventilation: decreased cardiac output

Other Risk Factors

- Polypharmacy: risk of adverse drug interaction increases with multiple medicatio
- Duration of hospital stay: 18 days—susceptible to hospital-acquired conditions ar subsequent drug therapy

CASE 3-2, QUESTION 2: The medical team is concerned that J.A.'s condition may have worsened; he may have had a neurologic event (e.g., stroke) in the night. J.A. is clinically unstable to bring to computed tomography (CT). The team needs J.A. to be alert for purposes of conducting a neurologic examination. To undergo the examination, J.A. must have his neuromuscular blockade discontinued and sedation lightened. One and one-half hours after discontinuation of cisatracurium J.A. is still not moving (TOF 0/4). The medical team feels J.A.'s cisatracurium's paralytic effect should have worn off by now and is concerned about his prognosis. The medical team ask the clinical pharmacist to review J.A.'s case and affirm that the neuromuscular blockade has worn off.

After reviewing the case, the clinician identifies potential drug-condition/disease and drug–drug pharmacodynamic interactions that may contribute to the prolonged neuromuscular blockade. These interactions are discussed below.

Background: The incidence of ICU-acquired weakness (polyneuropathy and myopathy) in ARDS patients is 34% to 60%. This condition can last for months to years and can severely affect a patient's quality of life.[76] There are several risk factors for ICU-acquired weakness that includes prolonged mechanical ventilation, number of days with dysfunction in 2 or more organs before wakening, corticosteroids, female sex,[77] toxins (e.g., botulism), neuromuscular disease states (e.g., Guillain-Barre Syndrome), severe electrolyte imbalances, prolonged recovery from neuromuscular blockers, deconditioning, length of vasopressor support, and hyperglycemia just to name a few.[76,78,79] Neuromuscular blockade alone has been associated with ICU-acquired weakness. However, in a multicenter, double-blind trial, investigators found no statistical difference in ICU-acquired paresis between cisatracurium and placebo groups at day 28 or ICU discharge.[78,80] Prolonged recovery from neuromuscular blockade may occur in patients with organ failure and/or conditions that affect the overall clearance of the neuromuscular blocking agent (e.g., decreased metabolism of a parent drug, decreased elimination of the parent drug, and/or the active metabolite). In addition to that, certain disease states, conditions, or drugs that may potentiate a blockade may also lead to an increased recovery time.[78,79]

Drug-Condition/Disease Interactions

PHARMACOKINETICS—DRUG METABOLISM/ELIMINATION

The nondepolarizing agent, cisatracurium, is a benzylisoquinolinium compound. It is one of the ten isomers of the intermediate-acting neuromuscular blocker, atracurium. It is primarily eliminated by Hofmann degradation; optimal breakdown occurs at physiologic temperature (37°C or 98.6°F) and pH (7.40).[72] This process results in therapeutically inactive metabolites, monoquaternary alcohol, monoquaternary acrylate, and laudanosine.[81] Cisatracurium's organ-independent elimination is a benefit for J.A. because he has renal and hepatic insufficiency. However, because cisatracurium is degraded by the Hofmann process, alterations in pH and temperature will affect the elimination of the drug. For example, the neuromuscular blockade effect is prolonged with acidosis while elimination is enhanced with an increase in pH. Additionally, hypothermia decreases the elimination of cisatracurium whereas hyperthermia accelerates it. In ICU patients, the recovery rate from neuromuscular blockade is reported to range from 45 to 75 minutes after discontinuation of a prolonged cisatracurium infusion.[82-84] Because J.A. has both a fever (101°F) and metabolic acidosis (pH 7.30 and HCO_3^- 19), it is difficult to predict the clearance of the neuromuscular blocker.

PHARMACODYNAMIC INTERACTION

A second condition that may add to J.A.'s prolonged blockade is his low phosphate (phosphate 0.9 mg/dL). Phosphate is a building block of adenosine triphosphate (ATP). ATP produces energy via an enzymatic reaction by releasing a phosphate group. This reaction is necessary for physiologic and metabolic functions including muscle contraction. Therefore, a patient with hypophosphatemia is at risk for a myopathy.[85]

Drug–Drug Interaction

PHARMACODYNAMIC—ADDITIVE EFFECTS OF MEDICATIONS

J.A.'s medications may also have additive effects with cisatracurium. A rare adverse effect of amikacin is neuromuscular blockade. The mechanism of blockade involves inhibiting acetylcholine release by competing with Ca^{+2} at the preganglionic nerve terminal and to a smaller degree noncompetitive blocking of the receptor.[86]

Corticosteroids (e.g., hydrocortisone) may also enhance blockade and increase recovery time. Proposed mechanisms for steroidal ICU-acquired weakness include increased muscle sensitivity to corticosteroids because of lack of movement and skeletal muscle atrophy from the steroid's catabolic actions. Additionally, corticosteroids may cause myopathy by denervation; corticosteroids have been shown to inhibit the nicotinic receptor; when combined with the neuromuscular blocking agent, vecuronium, this inhibition is potentiated.[76,87] It is thought that this interaction is more likely to occur with neuromuscular blockers that have a steroid structural ring, such as the aminosteroid (e.g., pancuronium, pipcuronium, vecuronium, and rocuronium). However, there have been case reports of prolonged paralysis with the benzylisoquinoliniums (e.g., atracurium, cisatracurium, doxacurium, mivacurium, and d-tubocurarine).[78,79,88]

J.A. may need a longer period than an hour and one-half to recover from his paralysis because of the following factors: decreased elimination of cisatracurium as a result of acidosis, hypophosphatemia, and medications (amikacin and hydrocortisone). J.A. should also have his phosphate slowly repleted.

CASE 3-2, QUESTION 3: The medical team asks you to explain the drug interactions affecting the antibiotic efficacy of J.A.'s regimen.

After reviewing the case, the clinician identifies potential drug–drug physiochemical interaction, as well as drug–condition and drug–drug pharmacodynamic interactions. The mechanism of action of these interactions is discussed below.

Drug–Drug Interaction

PHYSIOCHEMICAL INACTIVATION

It has been well documented that the coadministration of beta-lactam antibiotics with aminoglycoside antibiotics can lead to inactivation of the aminoglycoside. The mechanism involves the amino group of the aminoglycoside antibiotic forming an inactive amide with the beta-lactam ring of penicillin antibiotics.[89,90] Because penicillins have wide therapeutic index, this interaction primarily affects the efficacy of the aminoglycoside antibiotic.

This interaction has been shown to occur with the extended-spectrum penicillins (e.g., azlocillin, carbenicillin, mezlocillin, ticarcillin, and piperacillin). J.A. is currently on amikacin and imipenem–cilastatin antibiotics for treatment of a multiresistant organism. According to the literature, amikacin is the aminoglycoside that is least susceptible to this interaction.[90] Additionally, no inactivation of amikacin was observed when incubated in cilastatin 120 μg/mL human serum for 48 h at 37°C.[91]

This inactivation increases with contact time and is directly proportional to the concentration of penicillin.[92] The rate of elimination of aminoglycoside and imipenem–cilastatin may be increased because of J.A.'s renal dysfunction. This would increase the contact time of the medications.

Recommendations for J.A.'s antibiotic therapy include administration of medications separately; serum concentrations of aminoglycosides should be assayed immediately after drawn or if analysis is delayed freeze at −70°C; and because of his renal dysfunction, close monitoring of aminoglycoside serum concentrations is indicated.[92,93]

Drug-Condition/Disease Interaction

PHARMACODYNAMIC INTERACTION

The pharmacodynamic actions of amikacin may be decreased because J.A. is acidotic.

Amikacin enters the bacterial cell and reaches its site of action in three stages: ionic binding, energy-dependent phase I (EDP-I), and energy-dependent phase II (EDP-II) transport or uptake.

Ionic Binding to the Outer Membrane: At physiologic pH, amikacin (pKa 8.1) is a highly ionized basic cation. It binds to anionic lipopolysaccharides (LPSs), polar heads of phospholipids, and proteins on the outer cell membrane of Gram-negative bacteria and phospholipids and teichoic acids of Gram-positive bacteria.[94] This leads to displacement of cell wall Mg^{2+} and Ca^{2+} bridges that link LPS, and the result is the formation of pores in the cell wall where amikacin can enter into the periplasmic space.[95]

EDP-I: Amikacin is transported across the cytoplasmic membrane. EDP-I is dependent on pH and oxygen. Amikacin activity will decline in low pH and anaerobic conditions (e.g., abscesses).[95]

EDP-II: Amikacin is transported to the site of action, binding to the ribosomes.[95]

Drug–Drug Interaction

PHARMACODYNAMIC—ADDITIVE/SYNERGISTIC EFFECT OF MEDICATIONS

Penicillins form a covalent bond with the enzymes, the penicillin-binding proteins (PBPs) (specifically transpeptidase, endopeptidase, carboxypeptidase) inhibiting their action. These enzymes are needed for the final step of bacterial cell wall synthesis, the cross-linking between peptide side chains on the polysaccharide backbones of the peptidoglycan.[96] Cell wall inhibitors such as penicillins and vancomycin may expedite aminoglycoside entry into the bacterial cell resulting in synergistic effects when treating some organisms.[95]

J.A. is critically ill with renal failure, ARDS, pneumonia caused by a multiresistant organism, septic shock, and a metabolic acidosis. It is important to closely monitor his aminoglycoside therapy for efficacy (peaks) and toxicity (troughs).

This case illustrates the difficulties surrounding drug interaction identification, assessment, and follow-up intervention. Clinicians must recognize that literature to support the presence of a drug interaction is often scant and not always definitive and the optimal intervention may rely on clinical judgment. Refer to Chapter 56 for the Care of the Critically Ill Adult Patient.

CASE 3-3

QUESTION 1: D.T. is a 67-year-old Caucasian male who began taking imatinib about 10 years ago to treat a rare sarcoma: partially resected gastrointestinal stromal tumor (GIST). D.T. currently takes 600-mg imatinib daily, as well as rabeprazole and furosemide. He states that he is currently not taking any nonprescription medications. He continues to go to the cancer treatment center for continued monitoring. He contacts the cancer clinic to let them know that in 4 weeks he will be traveling to Africa to go on a safari. He mentioned that the friends that he will be traveling with told him that he will need malaria prophylaxis.

You are consulted regarding this request as the medical team wants to know whether there are any potential drug interactions and which antimalarial agent would be an appropriate selection.

Imatinib mesylate belongs to a class of drugs known as selective tyrosine kinase inhibitors (TKIs).[97] It inhibits the BCR-ABL tyrosine kinase, the constitutive abnormal tyrosine kinase created by the Philadelphia chromosome abnormality in chronic myeloid proteins.[97] It also inhibits the tyrosine kinase for platelet-derived growth factor (PDGF) and c-kit. TKIs, such as imatinib, are extensively metabolized via cytochrome P450 enzymes (with a large degree of interindividual variability).[98] Imatinib is metabolized primarily by CYP 3A4, whereas CYP1A2, CYP2C9, CYP2C19, CYP2D6, and CYP3A5 are reported to have a minor role in its metabolism.[99] In addition, imatinib is a substrate of human organic cation transporter type 1 (hOCT1), Pgp, and BCRP, though it is unclear whether imatinib is a substrate or inhibitor of BCRP.[100–103] Imatinib also competitively inhibits the metabolism of drugs that are CYP2C9, CYP2C19, CYP2D6, and CYP3A4 substrates.[104] It is also highly protein bound with approximately 95% bound to human plasma proteins.[99,105–107]

Drug–Drug Interaction

PHARMACOKINETICS—DRUG METABOLISM/ELIMINATION

There are several considerations of potential drug interactions with imatinib. Drug interactions should be considered when imatinib is administrated with other agents in the CYP3A family.[97] In particular, interactions are likely with inhibitors of CYP3A4, such as voriconazole or amiodarone, resulting in increases in the plasma concentration of imatinib. Concomitant use of rifampicin or other strong CYP3A4 inducers with imatinib should be avoided. In addition, concomitant administration of imatinib with agents that are both inhibitors of CYP3A4 and P-gp increases plasma and intracellular imatinib concentrations. Examples of dual CYP3A4 and Pgp inhibitors include verapamil, erythromycin, clarithromycin, ketoconazole, fluconazole, and itraconazole.[100,108,109] TKIs, such as imatinib, also can inhibit drug transporters and enzymes, resulting in changes in the exposure of coadministered drugs. St. John's-wort significantly altered the pharmacokinetic profile of imatinib with reductions of 30% in the medium area under the concentration–time curve (AUC). Patients should be cautioned regarding the concomitant use of products, such as St. John's-wort, as well as other inducers, that may necessitate an increase in imatinib dosing to maintain therapeutic efficacy.[110,111] Drug interactions involving protein binding of imatinib and other highly protein-bound drugs are not well understood.[97]

A study published in 2016 examined DDIs observed in patients treated with imatinib.[112] The investigators performed two observational studies to identify the medications that were most frequently dispensed simultaneously with imatinib through the French health insurance reimbursement database SNIIRAM (Systeme National d'Information Inter-Regimes Assurance Maladie), as well as the

---

ADRs related to DDIs involving imatinib using the French Pharmacovigilance Database. A sample of 544 patients from SNIIRAM with at least 1 reimbursement for imatinib were identified between January 2012 through August 2015. Of this cohort of 544 patients, 89.3% (486) of patients had at least 1 prescription medication that could potentially interact with imatinib based on mechanism of action (e.g., metabolism pathways). The results of the study also found that the most frequent DDI was with paracetamol (acetaminophen), (77.4%), which resulted in an increased risk of paracetamol toxicity. Other study findings with greater than 10% of patients with potential DDIs were with proton pumps inhibitors (33.3% for omeprazole) or dexamethasone (23.7%) that could reduce imatinib's effectiveness, and with levothyroxine (18.5%) that could decrease levothyroxine's effectiveness. The suspected mechanisms of this drug interaction with levothyroxine are an induction by imatinib of nondeiodination clearance or induction by imatinib of uridine diphosphate glucuronyl transferases.[113,114] Study results also found that the most frequently used drugs that could increase imatinib toxicity were ketoconazole and clarithromycin (respectively, 5.1% and 4.7%).[112] The overall findings of this study suggest that at least 40% of patients who are receiving imatinib are at risk of DDIs and may reach an even higher rate according to the results of the study performed in

SNIIRAM. The highest rate of potential DDIs in this study with imatinib was with the following agents: paracetamol, PPIs, dexamethasone, or levothyroxine. Based on the study findings, the investigators provided recommendations regarding the use of imatinib with specific agents. It is recommended that the reader refers to the package insert of imatinib for drug interactions and dosing guidelines. Further study regarding DDIs with imatinib, as well as other TKIs, is warranted.

With regard to selection of an antimalarial agent for D.T., chloroquine, mefloquine, and atovaquone-proguanil (Malarone) may have potential interactions with imatinib. The proguanil component is metabolized via the 2C19 pathway. Given the options that can be used for malaria prophylaxis in D.T., doxycycline would be an appropriate antimalarial agent used for malaria prophylaxis that does not interact with imatinib or D.T.'s other medications (Refer to Chapter 81 Parasitic Infections for malaria prophylaxis options). The most commonly reported adverse effects with doxycycline are GI effects, including nausea, vomiting, abdominal pain, and diarrhea. Esophageal ulceration associated with doxycycline is a rare but well-described adverse event. D.T. should be counseled to take doxycycline with food and plentiful fluids, in an upright position in order to minimize GI adverse effects. Because doxycycline can cause photosensitivity and D.T. will be on a safari, the risk of photosensitivity can be reduced by the use of an appropriate sunscreen and wearing protective clothing, including a hat. D.T. should also be counseled regarding the use of paracetamol (acetaminophen) and also to check in advance with his pharmacist before taking any natural products that may be metabolized via cytochrome P450.

RESOURCES AND EVIDENCE FOR CLINICAL DECISION SUPPORT

Healthcare providers have become increasingly challenged on devising optimal approaches to managing drug interactions. Patient safety initiatives have expanded in efforts to improve the healthcare delivery system with medication error prevention as a high-priority area. The consensus recommendations published by the expert group in 2015 have provided a road map for addressing the key concerns to improve the approach to evaluating DDI evidence for clinical decision-making.[5] As part of this process, it was important to review existing methods for evaluating DDIs. The Drug Interaction Probability Scale (DIPS), a 10-item scale, was developed to evaluate individual case reports for DDIs by assessing an adverse event for causality by a DDI.[115] This tool was developed to address limitations of previous assessment instruments, such as the Naranjo scale. The reader is referred to Appendix C of the consensus recommendations for further information regarding DIPS and other available instruments.[5] The expert group also discussed the current systematic approaches using clinical decision support (CDS) systems, their limitations, and the need for a new assessment instrument to objectively evaluate a body of evidence to establish the existence of a DDI. One of the key challenges of CDS systems is to determine what evidence is required for a DDI to be applicable to an entire drug class. Pharmacokinetic interactions are rarely generalizable to all agents within a drug class, and if there is class effect, the magnitude of the effect can often vary, which typically necessitates that each drug is reviewed individually. In some cases, pharmacokinetic interaction data may be extrapolated from one agent to other agents in the small class if the purported mechanism of interaction involves common pharmacologic effects.

To advance this important initiative, recently another group of experts convened to address the following: (1) to outline the process to use for developing and maintain a standard set of DDIs; (2) to determine the information that should be included in a knowledge base of standard DDIs; (3) to determine whether a list of contraindicated drug pairs can or should be established; and (4) to determine how to more intelligently filter DDI alerts.[116] Their recommendations for selecting drug–drug interactions for CDS were released in 2016. The reader is referred to both the 2015 and the 2016 recommendations.[5,116]

Because various avenues are examined to reduce the risk of drug interactions within society, it is essential as healthcare providers that we improve patient education regarding medication information. This strategy includes our communications with patients both verbal instructions and patient instruction leaflets given with the prescription. It is important to consider translation of information into different languages and to also promote culturally competent communication within every healthcare setting. The use of auxiliary warning labels placed on the medication package, books, and referring patients to quality health information on the internet. Pharmacists are uniquely positioned to provide important information regarding OTC medications, including herbal products when patients receive prescription information, and when they are seeking recommendations for OTC products.[117]

CONCLUSION

Given the complexities of data on drug interactions and the complexities within the healthcare systems, healthcare providers have become increasingly challenged on devising optimal approaches to managing drug interactions.[3] Patient safety initiatives have expanded in efforts to improve the healthcare delivery system with medication error prevention as a high-priority area. Medication errors may be related to professional practice, healthcare products, procedures, and systems, including prescribing, order communication, product labeling, packaging, nomenclature, compounding, dispensing, distribution, administration, education, monitoring, and use.[2,4] Because exposure to drug–drug interactions is a significant source of preventable drug-related harm, appropriate medication use, including drug interaction management, will avoid medication errors.[5]

Although the majority of drug interactions are clinically insignificant, in certain circumstances drug interactions are considered to be highly significant and can cause harm. Patients should be informed of the importance of maintaining a complete medication profile including over-the-counter medications, herbs, and dietary supplements. The incorporation of pharmacogenetic information into risk assessment of patients will improve our ability to prevent DDIs and to better evaluate interactions with biologic drugs.

More well-controlled studies are needed after drug approvals. Population-based studies are useful to determine the severity of, incidence of, and clinical importance of drug interactions. Pharmacogenetic research can further improve the precision of DDE evidence and CDS by identifying patient-specific predisposing factors. Future directives will identify the most appropriate process to rate the quality of DDI evidence and provided graded recommendations to reduce the risk of adverse consequences.[5]

Pharmacogenomics and Personalized Medicine

Shannon F. Manzi, Laura Chadwick, and Jonathan D. Picker

CORE PRINCIPLES	CHAPTER CASES
1 Pharmacogenomics is a single and important element of the broader concept of personalized medicine, which incorporates a variety of factors, both genetic and nongenetic, to guide targeted and individualized therapeutic decisions.	**Case 4-1(Question 1), Figure 4-1, Tables 4-1, 4-2, 4-3**
2 Pharmacogenomic effects can be both pharmacokinetic and pharmacodynamic in nature. Pharmacokinetic effects are observed when variants affect the absorption, distribution, metabolism, or excretion of a drug. Pharmacodynamic polymorphisms may result in variable amounts of drug target enzymes or receptors as well as possible changes in the drug target shape. These variations may render therapy ineffective or necessitate dose changes in certain affected populations.	**Case 4-2 (Questions 1, 2)**
3 DNA polymorphisms in drug-metabolizing enzymes can result in gain of function, loss of function, or no effect on function of the enzyme produced. In some cases, significant toxicity can result.	**Case 4-3 (Question 1), Figure 4-2, Table 4-4, Case 4-4 (Question 1), Table 4-5**
4 Drug transport proteins and binding targets can also be affected by pharmacogenomic variants.	**Case 4-5 (Questions 1,2), Table 4-6**
5 HLA genes are unique in that the presence of a variant does not impact the metabolism of a drug, but instead may indicate the likelihood of the development of a serious or life-threatening reaction.	**Case 4-6 (Questions 1, 2), Table 4-7**
6 Test interpretation is crucial to the practical application of pharmacogenomic data. In particular, CYP2D6 is a well-described cytochrome P450 enzyme responsible for approximately 25% of all drug metabolism. However, CYP2D6 is a complicated gene locus subject to multiple variants, pseudogene interference, and copy number variation.	**Case 4-7 (Questions 1, 2), Case 4-8 (Question 1), Table 4-8**
7 Age-based development adds a level of complexity when assessing pharmacogenomic markers in pediatric patients. Many of the pharmacogenomic dosing guidelines have not been validated in infants and children.	**Case 4-9 (Question 1), Figure 4-3**

8	Implementation of pharmacogenomics into practice currently faces many challenges including: the appropriate determination of when and whom to test; storage, analysis, and security of genetic data; and considerations for implementing pharmacogenomic data and recommendations into practice.	**Case 4-10 (Question 1), Case 4-11 (Questions 1, 2)**

"Pharmacogenomics" is the study and application of gene expression on drug pharmacokinetics and pharmacodynamics. This term is often used interchangeably with "pharmacogenetics." In the strictest of definitions, "pharmacogenetics" is used in the context of a drug response to a single gene, whereas "pharmacogenomics" refers to the broader study of the full genomic impact on drug behavior.[1] Because genetic variants are very specific to the individual, the use of pharmacogenomics in clinical practice has become a core component of the personalized medicine and precision medicine movements.[2,3] Ironically, the study of pharmacogenomics is not new. There are cases in the literature from the 1950s and 1960s describing the influence of a person's genetics on drug toxicity.[4,5] With the advent of newer, cheaper, faster deoxyribonucleic acid (DNA) sequencing techniques, the study of pharmacogenomics has exploded. In recent years, we have been able to begin transitioning that knowledge from the research realm to the clinic, although not without challenges.

A brief review of the basics of human genetics in the context of application to pharmacogenomics will be discussed in this chapter. Students are encouraged to utilize the selected references provided for this chapter for further review if needed. Although somatic "tumor" genetics, or the study of the mutations found in cancer cells, is a very timely and important consideration in antineoplastic drug selection and the treatment of oncologic processes, this chapter will primarily focus on the germline mutations in human DNA affecting drug absorption, distribution, metabolism, and excretion.

Human DNA is composed of 3 billion nucleotide base pairs, arranged on 46 chromosomes. There is significant variation in the genetic code from one person to another, creating what makes each of us unique—such as brown eyes, red hair, height, and heritable diseases. Included in the unique variations are changes in our ability to process medications. These differences are largely a result of variants in the nucleotide sequence on the genes responsible. The four nucleotides that make up the genes are adenine (A), guanine (G), cytosine (C), and thymine (T).

In most cases, but not all, two copies of each gene are present, one inherited from the mother and one from the father. Each copy is referred to as an "allele." If both the maternal and paternal alleles are the same, then the individual is considered homozygous for that allele or gene. If the parental copies differ, then the patient is considered to be heterozygous. Genes code for the production of proteins, such as enzymes, the structural components of cells, hormones, antibodies, and transport molecules. In pharmacogenomics, the gene and the enzyme often share the same name. For example, the gene that codes for cytochrome P450 CYP3A4 is known as CYP3A4 and the gene that codes for thiopurinemethyltransferase (TPMT) is known as TPMT.

When there is a change in the sequence or code, it is referred to as a variant. A change in a single base pair is commonly referred to as a single-nucleotide polymorphism or SNP (pronounced "snip") (Fig.4-1). Although the formal definition requires the variant to occur in at least 1% of the population, common usage does not differentiate on the basis of population frequency. A SNP that changes the function of the gene product is referred to as a mutation, and although not all SNPs are mutations, the terms are often used interchangeably. The location of the SNP is designated by a reference sequence number abbreviated "rsID." Many of the pharmacogenetic variants discussed in this chapter are SNPs and were originally found through genome-wide association studies (GWAS). Most GWAS are usually constructed to find common SNPs in a group of patients with the condition of interest and then subsequently define a level of association. These SNPs are responsible for 90% of pharmacogenetic variability and can result in gain of function (greater production of enzyme, or higher enzyme activity, than normal) or loss of function (decreased or no production of enzyme compared to normal).[3] Other changes can include deletions or insertions of larger segments of DNA and are commonly referred to as "indels." In many cases, indels terminate production of the protein.

In some cases, a change in a single allele is sufficient to affect drug metabolism. This occurs in dominant disorders. These occur because new mutations are passed from one individual to the next. Whether the ancestors exhibited symptoms or not likely depends on their own history and, of course, may not be known. In other cases, both copies of the gene must be defective in order for there to be a functional consequence. This occurs in recessive disorders, in which the parents are typically unaffected heterozygous carriers. One in four of their children will be at risk for inheriting the change and potentially exhibiting symptoms. As discussed earlier, this child may be homozygous if both parents have the same SNP, or it may be as a compound heterozygote, if each parent has a different dysfunctional SNP or mutation in the specific gene. Typically, in recessive disorders, there is otherwise no family history of any affected individual.

The resultant call or read of the variants gives us a genotype. The phenotype refers to the expression of that genotype. In some cases, this is visible, such as skin color or another physical characteristic. In other cases it is invisible, such as blood type or a less than normal amount of a Human Cytochrome P450 (CYP450) metabolizing enzyme. In the context of pharmacogenomics and the metabolizing enzymes, patients are often classified as having a phenotype of ultrarapid metabolizer, extensive metabolizers, intermediate metabolizers, or poor metabolizers based on their genotype.[6] There are several other phenotypes that will be discussed in the chapter, particularly those that deal with drug targets or pharmacodynamic responses.

The vast majority of drug metabolism pathways are not simply, a single enzyme resulting in one inactive metabolite that is immediately excreted by the body. Instead, most drugs utilize multiple metabolizing enzyme pathways, rely on several drug transporters, and have many metabolites of varying activity. Each of these steps may be subject to variable gene expression, coupled with indirect genetic and environmental effects on variables such as disease, weight, nutrition, age, and others. Add this complexity and it becomes evident how complicated pharmacogenomic interpretations can be.

Pharmacogenomics is unique in the field of genetics in that the representation of a person's genotype is noted by a "*," known as a star allele in the literature. For example, in many situations, the text representation of normal or "wild-type" variant status is *1/*1.[7] As other alleles are discovered, they are numbered sequentially *2, *3, etc. Inevitably, as discoveries are sometimes reported simultaneously around the world, there is occasionally an overlap of star alleles and the variants represented. There are several worldwide databases for reporting new pharmacogenomic variants, including the CYP Allele Nomenclature Database **http://www.cypalleles.ki.se/** and the Database of Genomic Variants **http://dgv.tcag.ca/dgv/app/home.**

During drug development and postmarketing analysis, it becomes clear that some patients will have severe adverse drug reactions (including nonresponse) after receiving the population-derived standard dose. These adverse reactions occur in the absence of medication error or lack of proper adherence to the drug. The Institute of Medicine "To Err is Human" report published in 2000 cited over 2 million reported adverse drug reactions in the United States per year, resulting in approximately 100,000 deaths at a cost of 20.6 billion annually.[8] It is estimated that 52% of U.S. adults are taking at least one prescription drug and 12% are taking more than five prescription drugs. If herbal products and over-the-counter drugs are included, then the estimates increase to over 80% and 29%, respectively.[6] It is well known that adverse drug reactions often go unnoticed and even more frequently unreported, making the actual numbers likely far higher. The clinical application of pharmacogenomics not only has allowed us to explain some of these historical reactions, but also helps clinicians predict who may be at higher risk for developing an adverse reaction if exposed to a drug or drug class.[9] Avoidance of adverse drug reactions has a measureable impact on a patient's quality of life, decreases overall health care costs, and lessens the time burden on health care providers managing the adverse reaction. However, acceptance of clinical pharmacogenomic testing is not universal and there remains the challenge of conclusively validating the genetic variant associated with the adverse reaction.[10]

ACGTTGGATGTACTTTTGAGGAAATGAG: Wild type sequence initially described

ACGTTGGATGTGCTTTTGAGGAAATGAG: A>G variant

The change from A to G at position 12 in this gene sequence results in a SNP.

PHARMACOKINETIC IMPLICATIONS

CASE 4-1

QUESTION 1: A.S. is a 2-year-old diagnosed with active multidrug-resistant tuberculosis (TB). The Centers for Disease Control and Prevention treatment protocol recommends isoniazid, rifampin, ethambutol, and pyrazinamide for initial therapy. Her mother is concerned because several family members in their home country of China had developed serious "liver problems" when they took isoniazid and she insists on the "gene test" for A.S. What genetic testing is A.S.'s mother referring to and what are the risks of toxicity in relation to isoniazid therapy?

Isoniazid is part of the four-drug regimen used to treat active TB and latent TB infection because it is bactericidal against Mycobacterium tuberculosis organisms.[11] One of the most commonly reported side effects leading to premature discontinuation of the drug is drug-induced liver injury (DILI). Significantly elevated hepatic enzymes are seen in up to 20% of patients, with progression to hepatitis in a smaller percentage of those treated.[12]

The metabolism of isoniazid is complex, with a key enzyme within the pathway being N-acetyltransferase-2 (NAT2).[11] NAT2 acetylates both the parent drug and a hydrazine metabolite, converting the hydrazine metabolite to acetyl hydrazine (AcHz).[12]An alternative metabolic pathway for hydrazine results in a toxic reactive metabolite. When NAT2 function is decreased, this pathway dominates, resulting in increased DILI and toxicity.

The production of the NAT2 enzyme is generated from a gene of the same name, with several known polymorphisms leading to alleles associated with either slow or rapid acetylation rates. Individuals homozygous for alleles associated with loss of function are considered "slow acetylators," those homozygous for alleles associated with gain of function "rapid acetylators," and heterozygotes "intermediate acetylators" (**Table 4-1**). DILI has been found to be highest in patients who are slow acetylators.[12] In addition to isoniazid, NAT2 is also a known acetylator of other drugs and/or metabolites, although the clinical effects of NAT2 genotype on these drugs are less well-studied, including: sulfonamides (sulfamethoxazole, metabolites of sulfasalazine), aromatic and aliphatic amines (procainamide, dapsone, metabolite of clonazepam, mescaline).[12]

The “gene test” mentioned by A.S.’s mother is likely a test for the NAT2 gene. A variety of pharmacogenomic tests are available to examine SNPs in the NAT2 gene and assign a patient’s genotype, either as part of a more extensive gene panel or as a targeted assay. Preemptive NAT2 testing prior to isoniazid therapy is not currently the standard of care; however, evidence suggests that in some populations with a high prevalence of DILI in slow acetylators, this may be beneficial.[14–18] Asian cohorts have been found to have the highest rates of DILI in the setting of a slow acetylator status (see summary of studies in **Table 4-2**). Although there are no formal dosing guidelines set for isoniazid therapy in the context of genotype or acetylator status, a study completed by Azuma et al. with 155 Japanese TB patients proposed a modified, genotype-based dosing regimen with successful clinically and statistically significant outcomes (results summarized in **Table 4-3**).[19]

There remain several pending questions as to how to most safely and appropriately incorporate NAT2 genotype results into a widespread clinical application. For example, pediatric patients such as A.S. offer a unique set of challenges, because recommended isoniazid starting doses are within a higher range (10–15 mg/kg), and dose modifications based on genotype have not been studied in this population.[13] Genotype concordance with predicted phenotype has also been found to be lower in pediatric patients.[20] Additionally, ethnic variation among study results also suggests that testing may be more beneficial in certain groups, namely those with Asian ancestry. As is the case when using ethnicity to determine whether or not to complete any genetic test, self-reported ancestry is not always a reliable means of predicting someone’s actual genetic lineage. With the generation of promising preliminary studies, a continued focus on NAT2 genotype effects on isoniazid safety has the potential to result in institutions and organizations adopting policies to proactively test NAT2 in the context of isoniazid treatment to both prevent adverse drug events and increase treatment success in the future.

PHARMACODYNAMIC IMPLICATIONS

CASE 4-2

QUESTION 1: E.F. is a 51-year-old male status post ST elevation myocardial infarction (STEMI) and atrial fibrillation with a residual left ventricular thrombus. Despite aggressive dose escalations of warfarin, his international normalized ratio (INR) will not budge above 1.7. His current dose of warfarin is 10 mg daily and he reports no dietary changes or excessive vitamin K intake. There are no drug–drug interactions identified in his regimen. The cardiology team asks about pharmacogenomic testing. What are the known genes involved in warfarin metabolism that would impact E.F.’s INR?

Table 4-1

NAT2 Genotypes and Phenotypes

NAT2 Allele Activity		
Slow	*5-7, *10, *12D, *14, *17, *19	
Rapid	*4 (wild type), *11, *12A-C, *13, *18	
NAT2 Phenotype Summary		
Genotype	**Acetylator Rate**	**Clinical Manifestation with Isoniazid Therapy**
Homozygous slow	Slow	Increased risk of adverse drug events
Heterozygous	Intermediate	
Homozygous rapid	Fast/rapid	Possible increased risk of treatment

[a] Shown in a small number of studies.[13]

Table 4-3

NAT2 Genotype-Based Dosing Recommendations for Isoniazid

Summary of Results from Azuma et al.[19]

	Genotype-Based Dosing Recommendation	**AE**	**Standard (5 mg/kg)**	**Genotype-Based Dosing**	**p**
Slow	50% dose decrease (˜2.5 mg/kg)	DILI	78%	0%	0.003
		TF	22.9%[a]	0%	NR
Intermediate	Standard (5 mg/kg)	DILI	4.7%		NR
		TF	26.8%		NR
Rapid	50% dose increase (˜7.5 mg/kg)	DILI	4.2%	4.6%	NS
		TF	38%	15%	0.013

DILI,drug-induced liver disease;TF,treatment failure; NR: no result; NS: nonsignificant.

Warfarin’s mechanism of action is to inhibit the Vitamin K Epoxide Reductase Complex subunit 1 (VKORC1), a key enzymatic component in the vitamin K clotting pathway.[21] By inhibiting VKORC1, synthesis of the vitamin K–dependent clotting factors II, VII, IX, and X is reduced and anticoagulation is achieved in conditions where thrombosis is a concern, such as atrial fibrillation. The amount of VKORC1 present in a person is linked to the VKORC1 gene, a key pharmacodynamic consideration. Patients with the GG genotype at VKORC1 rs9923231 are considered warfarin insensitive, meaning they are likely to require larger doses of medication to effectively inhibit the VKORC1 pathway. The AA genotype has been associated with lesser amounts of VKORC1, and therefore, these patients are considered to be warfarin sensitive and may require lower doses of medication for inhibition and anticoagulation.[22]

Another significant factor affecting warfarin dosing and response is the effect of genetic variants on warfarin metabolism. Warfarin is taken orally as a racemic mixture of R- and S-enantiomers, and its subsequent metabolism is complex, involving multiple genes and pathways. The primary pathway of the S-enantiomer, the active form of the drug, is via the CYP2C9 enzyme.[22] CYP2C9 is the predominant enzyme pathway responsible for more than 25% of the variation in warfarin metabolism. CYP2C9 is highly polymorphic, with several known variants within the population linked to reduced metabolic rates, including CYP2C9 *2 and *3 alleles. Reduced warfarin metabolism leads to increased concentrations of the active form of the drug. These patients may require lower warfarin doses, and thus may be at increased risk of bleeding using standard dosing algorithms.[22]

A more recent gene of focus with limited evidence relating to warfarin sensitivity is CYP4F2.[23] CYP4F2 affects the metabolism and therefore physiologic levels of vitamin K. Patients with the TT genotype for CYP4F2 rs2108622 are thought to maintain higher concentrations of vitamin K, and therefore require approximately 1 mg/day more warfarin than patients with the CC genotype.[23] Although current dosing models focus strictly on genotype for CYP2C9 and VKORC1 for warfarin initiation, CYP4F2 has shown early promise as a potential factor for strengthening the effectiveness of dose prediction algorithms in some ethnicities.[24]

It is important to remember that many nongenetic factors such as age, weight, diet, smoking status, and medication interactions contribute to a great variability of warfarin dosing among patient populations. Drug–drug interactions in which the CYP2C9 enzyme may be induced or inhibited will affect the rate of warfarin metabolism. Additionally, a diet high in vitamin K will make warfarin less effective, because this facilitates increased synthesis of vitamin K–dependent clotting factors. Algorithms for determining appropriate starting doses for patients over the age of 18 years based on both nongenetic and genetic factors are available at **www.warfarindosing.org**. Close monitoring of INR is also typically recommended to ensure proper anticoagulation and reduced risk of bleeding.

CASE 4-2, QUESTION 2: What other drugs are significantly affected by the CYP2C9 pathway?

CYP2C9 is estimated to play a role in the metabolism of up to 20% of commonly used medications.[25] From these medications, several associations have been found linking variants in the CYP2C9 pathway due to both increased rates of adverse drug events and variable medication response. Examples of such drugs include phenytoin, certain nonsteroidal anti-inflammatory drugs (such as celecoxib and diclofenac), sulfonylureas, losartan, and certain statins (such as fluvastatin and simvastatin). Patients with *2 or *3 alleles may be at increased risk of toxicities at standard doses of drugs that are processed through the CYP2C9 pathway decreased due to metabolism and increased parent drug concentrations and may require reduced dosing or increased monitoring.

TOXICITY IMPLICATIONS

Many known variants exist within the genes that code for enzyme proteins, affecting the rate at which the enzyme is able to metabolize drugs through its pathway. These variants may result in either reduced enzyme function and increased concentration of parent drug, or increased enzyme activity with decreased concentrations of a parent drug. The clinical effects of the variants depend on whether the parent drug is pharmacologically active or a prodrug.

CASE 4-3

QUESTION 1: T.B. is a 28 kg, 5-year-old male admitted for status epilepticus treated with IV lorazepam and IV fosphenytoin on presentation, aborting the seizures. Past medical history is significant for congenital hydrocephalus, a ventriculoperitoneal shunt and refractory epilepsy secondary to an in utero right middle cerebral artery stroke. On day 5 of his hospitalization, he is still extremely lethargic and his free phenytoin level is high, peaking at 3 mcg/mL on day 2 and 1.4 mcg/mL on day 5 (see **Fig. 4-2**). Looking at his records, he received an appropriate initial loading dose of IV fosphenytoin18 mg phenytoin sodium equivalents (PE)/kg (500 mg PE) followed by a single maintenance dose of IV fosphenytoin140 mg PE (5 mg PE/kg) 5 hours later on day 1 of the hospitalization. He has no clinically relevant drug–drug interactions and his albumin is normal. What is a possible reason for the toxicity T.B. is experiencing?

Phenytoin/fosphenytoin serum concentrations can be difficult to control and are complicated by multiple factors including Michaelis–Menton kinetics, also known as capacity limited metabolism. Drugs that follow Michaelis–Menton kinetics go from first to zero order, meaning that metabolism increases with increasing concentration until enzyme saturation takes place.[26] Once saturation is reached, drug plasma concentrations can increase to toxic levels in a fast and unpredictable manner. Additionally, many factors affect an individual's safe and effective phenytoin dose, including albumin levels, other medications in the patient's regimen, and pharmacogenetics.

Phenytoin has many chronic effects associated with long-term use, including hepatotoxicity, osteoporosis, megaloblastic anemia, gingival hyperplasia, hirsutism, and peripheral neuropathy.[27] In the acute setting of toxic plasma concentrations or an overdose, phenytoin toxicity can manifest with a variety of signs and symptoms, including CNS effects (dizziness, confusion, drowsiness, and ataxia) as well as GI upset and nausea. Phenytoin is also associated with severe cutaneous reactions such as Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) (see section with Case 4-6).

Fosphenytoin is a prodrug, converted by plasma esterases to the active drug phenytoin. Phenytoin is further metabolized by CYP2C9 to phenytoin arene-oxide, which is then broken down to multiple metabolites that are eventually excreted.[27] The contribution of these various metabolites to toxicity and efficacy of phenytoin is not well understood.

T.B. is found to have a loss of function variant status in CYP2C9 *1/*2. With loss of CYP2C9 enzyme function comes decreased breakdown of the active drug phenytoin at standard doses. Given the narrow therapeutic index of phenytoin and the drug's propensity to cause side effects, T.B. ultimately experienced drug toxicity and accompanying symptoms. The evidence relating genotypes such as T.B.'s to the development of adverse drug events is strong, and the Clinical Pharmacogenetics Implementation Consortium (CPIC, pronounced "See-Pick") has published dosing guidelines based on CYP2C9 genotype summarized in **Table 4-4**.[28] Note that only the maintenance, not the loading dose, has adjustment recommendations ensuring that acute seizure activity can adequately be terminated.

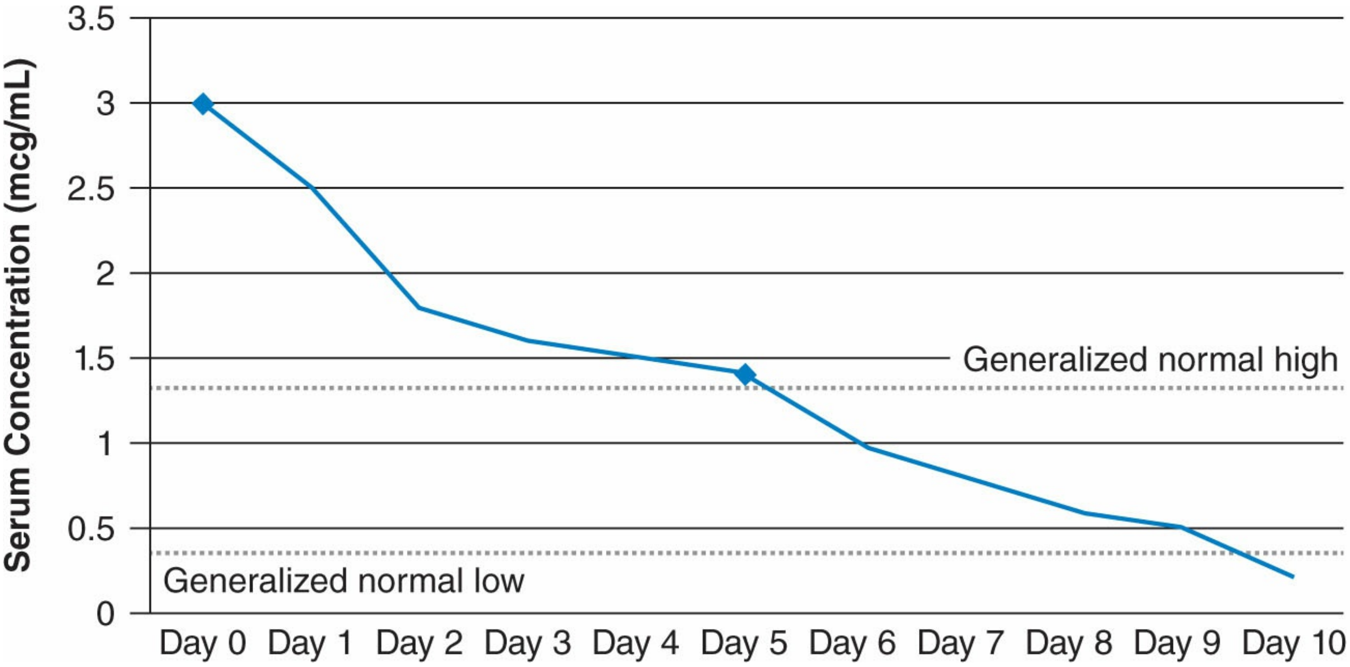

Figure 4-2 Free phenytoin levels (Case 4-3).

CASE 4-4

QUESTION 1: J.P. is a 50-kg, 17-year-old female, status post kidney transplant. She is currently receiving azathioprine 100 mg PO daily to prevent rejection. She is brought to the emergency department 5 days after starting the medication complaining of lethargy, fever, and malaise. A white blood cell count comes back as a critically low value at 900 cells/μL (normal range,3.8–9.8 × 10^3/μL), with an absolute neutrophil count (ANC) of 760 cells/μL (neutropenia defined as an ANC ≤ 2,000 cells/ μL). What factors might explain the severe neutropenia and what test should be ordered for J.P.?

Azathioprine is an immunosuppressive agent in the thiopurine class, acting as a prodrug of 6-mercaptopurine. These drugs are purine analogs and antagonize purine synthesis, inhibiting synthesis of DNA, RNA, and proteins.[29] Thiopurines are used in a variety of conditions including renal transplant, rheumatoid arthritis, certain cancers, and inflammatory bowel disease.

Azathioprine is metabolized to an active drug 6-mercaptopurine via glutathione S-transferase (GST) reduction. 6-mercaptopurine is then converted into the active 6-methylmercaptopurine ribonucleotide (6-MMPR) and several inactive metabolites such as 6-methylmercaptopurine (6-MMP) through multiple pathways.[30] The two primary enzymes contributing to 6-mercaptopurine breakdown are TPMT and hypoxanthine-guanine phosphoribosyltransferase (HPRT). Although TPMT metabolism results in the generation of the inactive metabolite 6-MMP, HPRT contributes to a pathway that leads to the generation of active 6-MMPR and 6-

thioguanine nucleotide (6-TGN) metabolites.[31] Furthermore, active 6-TGN metabolites are then inactivated by TPMT. The accumulation of active 6-TGN metabolites via HPRT is associated with myelosuppression with thiopurine therapy. In summary, TMPT acts as the detoxifying enzyme for drugs in the thiopurine class and its activity is directly linked to risk of drug toxicities.

The severe neutropenia J.P. experienced 5 days after beginning azathioprine is very likely the result of starting a full dose (2 mg/kg/day) in the setting of a homozygous variant TPMT genotype, such as *3B/*3C. Because of the near-absent enzyme level produced by homozygous variants, the TGN metabolites build up, resulting in severe and sometimes life-threatening neutropenia.

Table 4-4

CYP2C9 Genotype-Based Dosing Recommendations for Phenytoin/Fosphenytoin

CYP2C9 Metabolizer Status	Sample Genotype(s)	Recommendation
Extensive metabolizer	*1/*1	Initiate therapy with recommended maintenance dose
Intermediate metabolizer	*1/*2, *1/*3	Consider **25% reduction** of recommended starting maintenance dose and adjust according to therapeutic drug monitoring and response
Poor metabolizer	*2/*2, *3/*3, *2/*3	Consider **50% reduction** of recommended starting maintenance dose and adjust according to therapeutic drug monitoring and response

It is important to note that the genotype *3B/*3C is nearly impossible to distinguish from the less clinically impactful heterozygous genotype of *1/*3A on most commercially available TPMT assays. In cases of suspected homozygous variant status, parental studies may be necessary for absolute determination. Alternative therapy or a 90% reduction in the azathioprine dose is advised for J.P.'s TPMT genotype.[32] In the case of a heterozygous genotype such as *1/*3C, the dose would be decreased by 30%–70% (**Table 4-5**).[32]

DRUG TARGET IMPLICATIONS

CASE 4-5

QUESTION 1: L.K. is a 45-year-old woman referred for interpretation of pharmacogenomic results provided by a certified clinical lab as part of a research study. The report states that the called genotype for SLCO1B1 is CC. L.K. asks if she is at risk for severe muscle pain, or myopathy, which she heard about on a recent television malpractice commercial. What information do you need to answer her question?

Table 4-5

Summary of CPIC Guidelines for TPMT Genotype-Based Thiopurine Dosing

Phenotype (Genotype)	Sample Genotype(s)	Implication for Thiopurine Pathway	Thiopurine Dosing Recommendations
Normal/High Activity (Homozygous wild-type)	*1/*1	Lower concentrations of TGN metabolites	Start with normal starting dose and adjust doses of thiopurine based on disease-specific guidelines. Allow 2 weeks to reach steady state after each dose adjustment.
Intermediate activity (Heterozygous)	*1/*2, *1/*3A, *1/*3B, *1/*3C, *1/*4	Moderate to high concentrations of TGN metabolites	Consider starting at 30-70% of target dose for azathioprine and 6-mercaptopurine and 30-50% of target dose for thioguanine. Titrate based on tolerance. Allow 2-4 weeks to reach steady state after each dose adjustment.
Low/deficient activity (Homozygous variant/mutant)	*3A/*3A, *2/*3A, *3C/*3A, *3C/*4, *3C/*2, *3A/*4	Extremely high concentrations of TGN metabolites	Consider alternative agents. If using thiopurine, start with drastically reduced doses (reduce daily dose by 10-fold and dose thrice weekly instead of daily) and adjust doses based on degree of myelosuppression and disease-specific guidelines. Allow 4-6 weeks to reach steady state after each dose adjustment.

Source: MV Relling, EE Gardner, WJ Sandborn, et al. Clinical Pharmacogenetics Implementation Consortium Guidelines for Thiopurine Methyltransferase Genotype and Thiopurine Dosing. Clin Pharmacol Ther. 2011 Mar;89(3):387–91.

Table 4-6

SLCO1B1 Genotype-Based Dosing Recommendations for HMG-CoA Reductase Inhibitors

SLCO1B1 rs4149056 Genotype	Myopathy Risk with Simvastatin Use	Simvastatin Dosing Recommendation
TT	Normal	Prescribe standard starting dose and modify based on tolerance and disease response
TC	Intermediate	Prescribe a lower dose or consider alternative statin (such as pravastatin or rosuvastatin). Routine monitoring of CK may be considered
CC	High	Prescribe a lower dose or consider alternative statin (such as pravastatin or rosuvastatin). Routine monitoring of CK may be considered

“Statins” or HMG-CoA reductase inhibitor drugs are associated with muscle toxicity, ranging from mild aches to the development of severe debilitating myopathy and rhabdomyolysis in a segment of the population.[33] Regardless of severity, this adverse drug event is a common cause for drug discontinuation.[34] Recent published literature links this risk of developing these muscle-related side effects to certain variants in the SLCO1B1 gene.

Keeping in mind that a raw result from DNA analysis is essentially a string of A's, C's, T's, and G's within each individual gene, the CC genotype for SLCO1B1 information provided by L.K. is insufficient. In order to review available evidence, it is essential to know the actual variant location that the CC call was based upon. Although there are multiple polymorphisms that have been identified in the SLCO1B1 gene, only few are linked to clinical effect.[35] The majority of laboratory interpretation will call out the relevant rs numbers needed to make a pharmacogenomic determination of drug selection and dose alteration. An rs number, or rsID, is used to point to a specific nucleotide location within a gene. Known SNPs within a gene are defined by rsID for the purpose of clinical guidelines and research reporting. This ensures standardization and proper assessment of variants. For SLCO1B1, the rsID most commonly associated with development of myopathy with HMG-CoA reductase inhibitors is rs4149056.[35] This rsID should be provided with any result in order to make the proper assessments and recommendations.

CASE 4-5, QUESTION 2: The clinical lab confirms the SLCO1B1 genotype CC call was based on rs4149056. What is your answer to L.K.'s question regarding her risk of developing severe myopathy?

The C allele at SLCO1B1 rs4149056 has been associated with decreased statin intracellular transport and clearance.[34] SLCO1B1 is a transporter protein with a primary function of drug uptake into the liver. Variants affecting the hepatic uptake of drugs via SLCO1B1 ultimately increase overall area under the curve and drug exposure, resulting in higher risks of adverse drug events such as myopathy. Patients with homozygous variant status such as L.K. are at significantly increased risk of developing muscle toxicity with statin use. Although all statins may have adverse event profiles linked to this variant, the evidence is strongest for simvastatin. Published CPIC guidelines for simvastatin with SLCO1B1 rs4149056 variant status are summarized in **Table 4-6**.

NONMETABOLISM IMPLICATIONS

CASE 4-6

QUESTION 1: J.C. is an 18-year-old female with a past medical history of epilepsy. Following a failed course of levetiracetam, her physician has decided to start her on carbamazepine therapy for seizure control. Approximately 2 months after starting the drug, J.C. is seizure free but feels as though she is coming down with what feels like a cold with accompanying headache and fever. She also begins to notice that her skin is becoming red and itchy in several locations. The rash quickly progresses to the point where she notes swelling and the formation of blisters on her nostrils, eyes and lips. J.C. realizes that she is experiencing something more than a common cold and rash, and calls the pharmacy in a panic to ask if it is possible that she is reacting to her medication, even though she has been on it for some time. Given the known side effects of carbamazepine, is it possible that J.C.is reacting to the medication?

Adverse drug reactions are often thought of as happening acutely following initial doses of medications; however, delayed hypersensitivities are also possible with certain drugs. In the case of carbamazepine, these reactions are linked to DNA changes within the human leukocyte antigen (HLA) genes. There is a strong association between positive HLA-B*15:02 gene variant carrier status and increased risk of severe cutaneous adverse reactions.[36] A less established link has also been seen with carriers of the HLA-A*31:01 variant, more common in Japanese and Caucasians.[37]

The HLA genes code for proteins that form an immunologic complex on all nucleated cells. This complex is responsible for presenting both self- and foreign peptides to immune cells, such as T-cells.[38] When a foreign peptide is presented and then recognized by a T-cell, an immunologic response results. Examples of peptides that may be recognized as foreign include viruses, bacteria, tumor antigens, and drugs. Although this may be the basis for the drug-induced reactions seen with the described HLA variants, there is still significant uncertainty that this is truly the only mechanism in play. Evidence has suggested that drug concentrations are also higher in patients who experience cutaneous reactions, meaning that CYP loss-of-function alleles as well as HLA variants may work synergistically to increase a patient's risk of SJS and TEN.[39] This is supported by the fact that not all patients who carry an HLA allele will experience a cutaneous reaction.[38]

HLA Class I genes are highly polymorphic.[40] Variants within these genes are thought to result in structural changes in the HLA complex that increase the recognition and subsequent response of the immune system to certain drugs, resulting in hypersensitivity. Reactions related to these variants tend to be dermatologic in nature with or without systemic involvement, ranging from a mild maculopapular rash or progressing to more severe cases of SJS and TEN.

CASE 4-6, QUESTION 2: What is the appropriate advice for the pharmacist to provide to J.C. given her presentation?

J.C. should be advised to seek care immediately at the closest and most accessible hospital emergency department. SJS and TEN have significant associated complications, and typically require inpatient treatment with fluids, corticosteroids, analgesics, nutritional supplementation, and antibiotics. Mortality rates with TEN are estimated to be higher than 30%.[38] In all cases, the suspected offending agent should be discontinued with no attempt to rechallenge.

CASE 4-6, QUESTION 3: In questioning J.C., the pharmacist learns that she has no prior history of adverse drug or food reactions. She is of Chinese descent, and has never had genetic testing. What would have been the more appropriate course of action for a patient with J.C.'s history prior to starting carbamazepine therapy?

Table 4-7

HLA Variants, Affected Drugs, and Population Incidence

HLAVariant	Drugs with Associated Adverse Cutaneous Reactions	Highest Variant Frequencies by Ethnicity
HLA-B*57:01	Abacavir	Caucasian: 5%–8%
HLA-B*58:01	Allopurinol	Han Chinese: 6%–8% Korean: 12%
HLA-B*15:02	Phenytoin, Carbamazepine	Han Chinese: ˜10%[44] Populations from Hong Kong, Thailand, Malaysia, Vietnam, Philippines, India, and Indonesia: >5%
HLA-A*31:01	Carbamazepine	Northern European: 2%–5% Japanese: 9% Chinese: 3.7%[45]

Carriers of certain HLA variants are at increased risk of cutaneous adverse drug reactions; however, recommendations and guidelines for preemptive testing are either nonspecific or lacking. Other HLA variants have been linked to liver injury, leading to the theory that the burden of HLA expression may be an important factor in the organ systems affected.[38] Much is left to the provider or institution-specific protocols to determine when and whom to test prior to therapy. An exception to this is the antiretroviral medication, abacavir, for which CPIC and FDA recommendations are in place stating that all patients should have HLA-B*57:01 testing before initiating this regimen.[41]

Of note, HLA variants are reported as positive (at least one variant present) or negative (no variant present). Variants of the HLA genes are seen more commonly within certain ethnicities. In some cases, because of the high prevalence of allele carrier status in these populations, patients with particular ethnic backgrounds may be recommended for testing. Certain Asian populations in particular are known to have higher rates of certain variants, warranting caution when using particular therapies (see **Table 4-7**). In the case of carbamazepine and J.C., her physician may have justifiably ordered pharmacogenomic testing to determine her HLA-B*15:02 carrier status on the fact that she identifies as Chinese. Relying on self-reported ethnicity can be problematic, however, as many people are not fully knowledgeable of their complete lineage.

Although recommendations for testing vary, for every drug with established clinical guidelines, if a patient is a known carrier of an HLA variant, it is recommended that they avoid the use of drugs for which there is an HLA variant–associated risk of adverse reaction.[38,42–44]

THE PECULIARITIES OF CYP2D6

CASE 4-7

QUESTION 1: P.F. is a 37-year-old female with a history of depression and anxiety who presents to the local pharmacy with a printed report from a for-profit pharmacogenomic testing company. The report states that P.F. is an extensive metabolizer for CYP2D6 and she is concerned that her paroxetine is still not providing any relief of her depressive symptoms despite having taken the drug correctly for the past 3 months. What information do you want to know about the testing modality the company used prior to answering her question regarding the interpreted genotype?

There are several pharmacogenomic testing platforms available. The vast majority of panels that are available commercially are SNP based. The advantages to SNP-based platforms include a lower cost, faster turnaround time, vendor-provided interpretation software, and reliable calling for known variants. The main disadvantage to the SNP-based platforms is that the user is limited only to the genes and specific variants on the panel. If there are any unique or rare variants, the SNP-based panel will not detect them. Therefore, the patient's reported genotype will not match their phenotype (how they actually respond to the drug). Additionally, in the case of CYP2D6, it is a very polymorphic gene that frequently has more than two copies. This is referred to as copy number variation (CNV) and is extremely important in the interpretation of a patient's CYP2D6 genotype.[46,47] All of the copies should be typed, and this is not always possible on commercially available assays because it requires extra primers and interpretation algorithms. Another issue is that CYP2D7 is a pseudogene (a gene with no function) that can be accidentally included in the CYP2D6 assay if it has not been designed correctly.[48]

Pharmacogenetic data can be the by-product of other genetic assays as well. The exome is considered the workhorse or coding region of the DNA. Whole exome sequencing or sequencing of targeted regions of interest can provide significant pharmacogenomic data as long as the level of coverage of the genes of interest is adequate. This may include variants that may have only been reported once or twice before in the literature or variants of unknown significance (VUS). These findings become a challenge to manage and to provide meaningful interpretation to the patients. Additionally, in both exome and whole genome sequencing, incidental or secondary findings of disease state markers will become paramount to deal with making the case for pharmacogenomics (see section with Case 4-8). The hybrid test, a sequence-based targeted panel of pharmacogenes, has become a hot area of development, attempting to incorporate the best features of both sequencing and limited gene interrogation.

In the case of P.F., the report shows a genotype of CYP2D6 *1/*2 but does not indicate the copy number of the CYP2D6 gene. This is a red flag for interpretation and should prompt the pharmacist to call the company to obtain a detailed explanation of the assay used and how the interpretation of extensive metabolizer was determined.

Table 4-8

CYP2D6 Genotypes, Phenotypes, and Activity Scores

Number of Copies	Genotype	Activity Score	Phenotype
≤2	*1/*2	1.0–2.0	Extensive metabolizer
>2	*1/*2	2.0	Ultrarapid metabolizer

CASE 4-7, QUESTION 2: Per the company, the copy number was equal to 3. Does this change the interpretation of P.F.'s phenotype?

With a copy number of 3, a genotype of CYP2D6 *1/*2 is associated with an ultrarapid metabolizer phenotype.[49] Unique to CYP2D6, an activity score is calculated based on the number of copies of the gene present as all contribute toward drug metabolism. The activity score was described by Gaedigk[46] to better categorize the metabolism status of persons with multiple copies of the gene. An example of how this can change a phenotype is represented in **Table 4-8**.[46]

The lack of response demonstrated by P.F. to the standard dose of paroxetine fits the phenotype of an ultrarapid metabolizer. The recommendation per the CPIC guideline would be to choose another drug not primarily metabolized via the CYP2D6 pathway.[47] This case provides a prime example of how time can be wasted and patient morbidity increased due to lack of response when pharmacogenomic markers are not considered prior to initiating therapy.

CASE 4-8

QUESTION 1: You have started work at a pediatric hospital and notice that codeine is not orderable in the electronic medical record. When you ask a coworker, they inform you that the black box warning placed on all codeine products by the FDA in 2012 has resulted in the majority of pediatric institutions removing the drug from the formulary. What genotype is correlated with the risk of life-threatening apnea?

Codeine is metabolized by CYP2D6 to the active metabolite morphine, which provides analgesic properties. For patients with the ultrarapid metabolizer status described earlier, the amount of morphine generated can exceed the body's ability to convert to less toxic metabolites, resulting in life-threatening apnea.[48] The ultrarapid metabolizer phenotype is found in up to 4% of the population.[49] In contrast, there are several loss-of-function variants with far-ranging incidence across ethnicities. For example, the *4 allele is found in 6% of African-Americans, 5% of Asians, and up to 18% of European-Americans/Europeans.[50] These variants confer little to no enzyme function, resulting in lack of morphine formation. Patients with these genotypes will not have the desired analgesic response to codeine.[50]

DEVELOPMENTAL IMPACT AND PHARMACOGENOMICS

CASE 4-9

QUESTION 1: As part of a voluntary research study in the NICU, pharmacogenomic results are returned to the provider for a baby girl born at 30 weeks, who is now at corrected 36.5-week gestational age. The provider notes that the genotype is CYP2C19 *17/*17 gain of function, indicating she is an ultrarapid metabolizer. The provider states he would like to start her on voriconazole for a presumed fungal infection and asks what the dosing should be in context of her genotype. What other information would be necessary to recommend a voriconazole dose for this baby?

Voriconazole is metabolized by CYP3A4, CYP2C9, and CYP2C19, with the most significant contribution coming from CYP2C19.[9] The Royal Dutch Pharmacists Association has guidelines in place recommending monitoring of voriconazole serum concentrations for CYP2C19 poor and intermediate metabolizers, as these patients have been found to have higher concentrations of active drug and increased risk of toxicity. The consideration for a person with the CYP2C19 *17/*17 is the potential for increased breakdown of active drug and treatment failure.[51]

Given this patient's age, there are multiple complex factors that need to be considered for dosing, both genetic and nongenetic. As voriconazole is dosed by body weight, the actual body weight of the child is necessary for an appropriate dose calculation.[52] Drug–drug interactions may also need to be considered in the event that the patient is receiving medications that induce or inhibit enzymes in the drug's pathway. Other variables also contributing to complicated infant dosing and clearance unpredictability include developing gastrointestinal and renal function and fluctuations in body fat and water composition affecting volume of drug distribution.[53] Additionally, although the patient's genotype suggests that she will have increased breakdown of the active drug, it is known that regardless of genotype, humans are not born with fully functional CYP enzymes.[53]

CYP enzyme development occurs at variable rates over time making it difficult to determine the contribution of pharmacogenomic variants on optimal dosing (see Fig. 4-3). An excellent summary review of enzyme maturation by Kearns and colleagues was published in the NEJM in 2003.[53] CYP1A2, for example, is virtually undetectable at birth, with initial development of low-level enzyme concentrations observed over the first month

of life.[54,55] Although general trends are observed, it is also understood that among individuals, development rates vary throughout childhood, particularly in the first year of life.[54] Given this consideration, pharmacogenomics in the infant population may be less of reliable factor than it is in adults, and its overall contribution remains unpredictable as few studies are dedicated to the effects of pharmacogenomic variants in younger individuals. Therefore, it is particularly important in children and infants to monitor for drug concentrations, response, and toxicities, and to adjust dose accordingly.[55] Voriconazole is of particular concern with this group, with evidence suggesting that current pediatric dosing recommendations may lead to subtherapeutic concentrations and a general increased risk of treatment failure.[55]

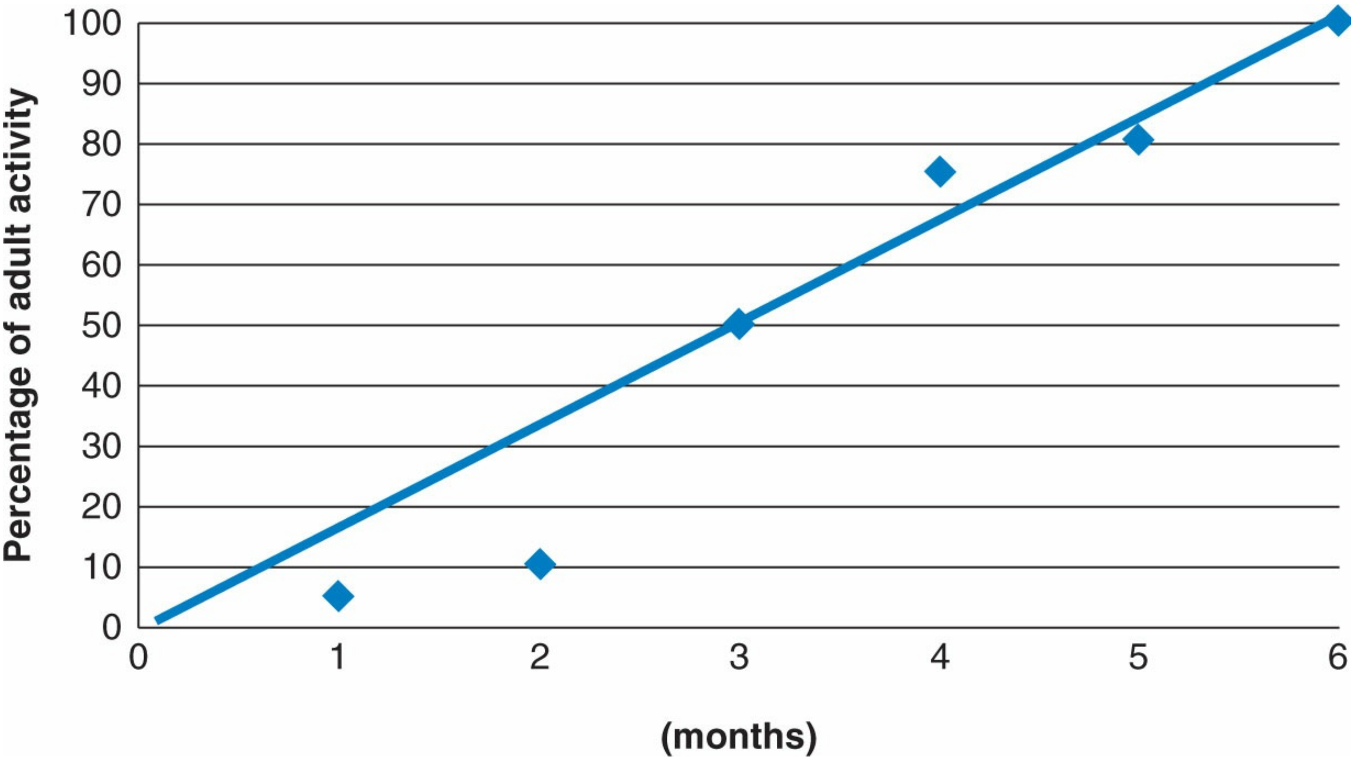

Figure 4-3 CYP2C19 enzyme activity by age.

FAMILY IMPLICATIONS OF PHARMACOGENETICS

CASE 4-10

QUESTION 1: A 12-year-old-girl has an operation and develops malignant hyperthermia (MH) upon initiation of anesthesia. Subsequently, she is found to have a c. 7300G>A mutation in the RYR1 gene, a common variant associated with predisposition for MH. Following her recovery and discussion of future medical and drug management, what else would be important to discuss?

Genes are inherited; therefore, any discussion of genetic variants must be undertaken with an awareness of the greater implications of any identified changes. In this case especially, because the consequences of the gene change are so profound and the mutation is a dominant one, it is likely that she inherited the change. An exploration of the family history may suggest that one parent is more likely to be the carrier than another, and counseling with a view toward testing may well be guided by such information. Furthermore, one must consider the potential for siblings, grandparents, and the extended family to be affected depending on the severity of the variant status and the clinical picture.

In the situation where the individual is being counseled for pharmacogenomic testing presymptomatically, it is important to raise the possibility that the results may have implications for the greater family before testing is undertaken.[58]

MAKING THE CASE FOR PHARMACOGENETICS

Pharmacogenomics has allowed pharmaceutical companies to design and develop drugs specifically targeted at certain mutations. In order to determine the right patient for the drug, companion tests (pharmacogenetic assays that target the variants of interest) are usually required. The pharmacist must understand which medications require companion testing and be able to interpret the results. Although up to 50% of drug companies are pursuing drug targets that would require companion genetic tests, there are several hindrances that must be addressed, including potential delays in companion test approval and potentially decreasing the patient base by eliminating those who would otherwise be prescribed the drug in the absence of knowledge of the genetic marker presence.[2] Additionally, several studies have shown that patients are more adherent with their medications after having personalized genotyping, even if the results show “normal” enzyme function.[59]

CASE 4-11

QUESTION 1: K.D. is a 22-year-old female with cystic fibrosis. Her pulmonologist is interested in the new drug ivacaftor, but is unsure what testing is required to start therapy. What testing is necessary and which variants qualify for ivacaftor therapy?

Ivacaftor (Kalydeco) is a drug for cystic fibrosis that targets ten specific variants in the Cystic Fibrosis Transmembrane Regulator (CFTR) gene. If a patient has a variant status other than G551D, G1244E, G1349D, G178R, G551S, R117H, S1251N, S1255P, S549N, or S549R, the drug will be ineffective.[60]

The CFTR gene codes for the CFTR protein on a variety of tissue surfaces, including the lungs. When functioning properly, the CFTR protein is a key component in maintaining intracellular salt balance.[61] In cystic fibrosis, because of a variety of possible genetic mutations the CFTR protein fails to function properly leading to fluid imbalances, the buildup of secretions, and several related complications. Ivacaftor acts as a CFTR potentiator increasing chloride ion transport, restoring electrolyte balance, reducing the buildup of secretions, and improving health outcomes such as pulmonary function and weight gain for affected patients.[62] The approval of this drug in 2012 for patients with the G551D mutation offered promise for continued future development of therapies targeting causes of disease that are genetically associated. This promise remains encouraging as the use of ivacaftor has since been approved in the treatment of several additional gene mutations, and new similar targeted therapies such as lumacaftor (Orkambi), a CFTR corrector, continue to enter the market.[63]

Another potential use of pharmacogenomics involves salvaging drugs with high toxicity profiles. Historically, drugs have been taken off the market after an unacceptable number of patients either suffered significant morbidity or mortality secondary to the use of the drug. In some cases, pharmacogenomic studies may be able to determine which patients could continue to benefit from the drug and which for patients' use must be avoided.

Despite all of the advances in testing and application, pharmacogenomic preemptive testing (testing prior to the development of an adverse effect or lack of response) is not currently in wide use. There are several reasons for this. The lack of knowledge by healthcare professionals, including pharmacists, is a large barrier. One recent study demonstrated that only 29% of the physicians surveyed had received any formal education and only 10.3% felt knowledgeable enough to prescribe or discuss the results of pharmacogenomic testing.[64] Another large impediment to implementation is the lack of consistent reimbursement by insurance providers. Consistent coverage by insurance companies will require regulatory effort and additional proof that pharmacogenomic testing improves outcome and decreases cost.[2]

Therefore, at this time, the majority of preemptive testing is being done in academic medical centers, in cancer centers, or by for-profit pharmacogenomic testing companies that can either institutionally support the development of the programs or can directly bill for the services not covered by insurance.

CASE 4-11, QUESTION 2: What references could be used to assist in interpretation of pharmacogenomic markers and subsequent drug dosing recommendations?

Currently, the FDA lists pharmacogenomic markers in 190 drug labels and the European Medicines Agency lists pharmacogenomic information in 78 drug labels.[65,66] In order to be included in the FDA labeling, the pharmacogenomic marker must have actionable data, such as an increase in adverse effects or reduction in efficacy

in patients with certain variants. Guidelines for drug dosing and selection have been developed by the Clinical Pharmacogenomics Implementation Consortium (CPIC) and the Pharmacogenetics Working Groups of the Royal Dutch Pharmacists Association (DPWG). Each guideline is rated on the level of evidence available to support the recommendation. Currently, there are 36 CPIC Level I evidence published guidelines available on www.pharmgkb.org, a website supported by the NIH and hosted by Stanford University.[67] The site houses a wealth of information including pathway diagrams, annotated bibliographies, and lookup tables. It is important to note, the guidelines do not address who should be tested, but instead focus on what to do with the data if it is available.

Incorporating pharmacogenomic data into the electronic medical record systems used by many hospitals, clinics, pharmacies, and primary care offices is challenging at best. Result reports from the laboratories capable of running these tests are rarely in a machine-readable format and are generally scanned as pdf documents to the medical record.[68] This becomes a major challenge for the system to be able to provide relevant pharmacogenomic data at the time it is needed, usually during prescribing of a drug. Results of this type that persist throughout a person's lifetime and are relevant all along the continuum require significant bioinformatics expertise to house, retrieve, interpret, and present to the end user at the right time.[69] Additionally, understanding that the testing will evolve over time, either resulting in the need to sequence a new sample or ideally, reanalyzing the previously deep sequenced sample with new algorithms to apply the most recent variant knowledge. A payment model for reinterpretation without retesting is extremely uncommon in the field of laboratory medicine today.

Another extremely important consideration is data security and privacy. Data security refers to the ability to protect information from breaches and inadvertent dissemination. Data privacy refers to the ability to respect patient preference for data sharing, both with the patient themselves and with the larger health care community.

How is the decision made to offer and incorporate pharmacogenomic testing into practice? In some cases, it becomes forced upon the healthcare provider, such as a pharmacist or primary care physician, who is handed a printed report by a patient who has purchased direct to consumer pharmacogenetic testing services and insists that the information be considered when prescribing and dispensing decisions are made. Clearly, that is a less than ideal situation. Healthcare provider education has begun to incorporate pharmacogenomic science into the core curriculums, but it is often in the form of a single1-to 2-hour lecture. This will be inadequate preparation to deal with the era of personalized medicine and the eventual day when everyone will have access to their own genomic data.

When assessing a pharmacogenomic test for potential incorporation into practice, several factors impact the return on investment and clinical outcome. These include but are not limited to the number of patients needed to be tested in order to find one patient with an actionable variant (also known as the incidence of variant status) and the ethnic variation, being cognizant that we are becoming a very blended population without full knowledge of our entire ancestry. Additionally, institutions must investigate how much each test costs to run, if it will be reimbursed, and what are the cost savings offset by averting serious adverse reactions or the consequences of nonresponse.[2,70,71]

Genetic testing can introduce ethical questions that can be challenging, particularly when dealing with sequencing large portions of the DNA. Although most people want to know whether or not they should take a medication, many do not wish to know their risk of developing Alzheimer disease or breast cancer. This becomes a concern with some of the broader sequencing tests such as whole exome or whole genome. The American College of Medical Genetics and Genomics (ACMG) released a position statement in 2013, recommending mandatory reporting in 24 categories of diseases caused by genetic variants whenever a sequencing test is performed, regardless of patient preference around wanting to know that information and irrespective of age of the patient.[72] Arguments against this practice have included the patient's right to decide, informing the parents/caregivers of an adult-onset disease for a child, and insurance discrimination risks.[73,74] Although it is illegal for health insurance coverage to be denied due to genetic findings following the passage of the Genetic Information Nondiscrimination Act (GINA) in 2008, this is currently not true for life or long-term care insurance coverage.[75]

CONCLUSION

Pharmacogenomics is simultaneously an exciting and challenging component of personalized medicine and the practice of pharmacy. One of the most important points to remember is that pharmacogenomic information is an additional clinical marker, but is rarely the only answer. A patient's organ function, disease state, diet, smoking status, other environmental factors, and drug–drug interactions play a very large role in the disposition of drugs. Age-based maturation of enzyme function must also be accounted for when determining the impact of the genotype on drug metabolism.

Pharmacists are uniquely qualified to interpret and apply pharmacogenetic findings to medication recommendations. However, this will require adequate preparation, application of validated algorithms, access to continually updated literature, and a partnership with genetic experts, including geneticists and genetic counselors.[76]

Managing Drug Overdoses and Poisonings

Iris Sheinhait and Sara Zhou

CORE PRINCIPLES	CHAPTER CASES
EPIDEMIOLOGY	
1 In 2013, 2.2 million poisonings were reported to the American Association of Poison Control Centers. Half of these exposures occur in children younger than 5 years of age and usually involve a single substance that is found in the home such as personal care items, analgesics, and cleaning agents. The most common exposures in descending order include cosmetic/personal care products, household cleaning agents, analgesics, toys and foreign bodies, and topical preparations.	**Case 5-1 (Questions 2, 3), Table 5-1**
GENERAL MANAGEMENT	
1 The most important aspect of patient management is to support airway, breathing, and circulation (the "ABCs"). There is no "cookbook" method to treat all poisoned patients, so it is important to treat the patient, not the poison or the laboratory values. The assessment and treatment of the potentially poisoned patient can be separated into seven functions: (a) gather history of exposure, (b) evaluate clinical presentation (i.e., "toxidromes"), (c) evaluate clinical laboratory patient data, (d) remove the toxic source (e.g., irrigate eyes, decontaminate exposed skin), (e) consider antidotes and specific treatment, (f) enhance systemic clearance, and (g) monitor patient outcome.	**Case 5-4 (Questions 1, 3, 5, 6)**
GASTROINTESTINAL DECONTAMINATION	
1 The most appropriate method for gastrointestinal (GI) tract decontamination is unclear because sound comparative data for different methods of GI decontamination are not available. Lavage, emesis, and cathartics are rarely performed as there is no evidence they improve patient outcome. Activated charcoal is generally safe to use, but it should not be administered if the benefit is not greater than the risk. Whole bowel irrigation using a polyethylene glycol–balanced electrolyte solution can successfully remove substances (iron, lithium, sustained-release dosage forms) from the entire GI tract in a period of several hours.	**Case 5-3 (Questions 6, 7), Case 5-4 (Questions 11, 12, 16), Case 5-5 (Question 3)**
ANTIDOTES	

1 An antidote is a drug that neutralizes or reverses the toxicity of another substance. Some antidotes displace drugs from receptor sites (e.g., naloxone for opioids, flumazenil for benzodiazepines), and some can inhibit the formation of toxic metabolites (e.g., N-acetylcysteine [NAC] for acetaminophen, fomepizole for ethylene glycol and methanol).	**Case 5-4 (Questions 2, 4)**

TOXICOLOGY LABORATORY SCREENING

1 An antidote is a drug that neutralizes or reverses the toxicity of another substance. Some antidotes displace drugs from receptor sites (e.g., naloxone for opioids, flumazenil for benzodiazepines), and some can inhibit the formation of toxic metabolites (e.g., N-acetylcysteine [NAC] for acetaminophen, fomepizole for ethylene glycol and methanol).	**Case 5-4 (Questions 2, 4)**

TOXICOLOGY LABORATORY SCREENING

1 Urine drug screens can be useful in a patient with coma of unknown etiology, when the presented history is inconsistent with clinical findings, or when more than one drug might have been ingested. Qualitative screening is intended to identify unknown substances involved in the toxic exposure. A benzodiazepine screen can detect oxazepam, a common benzodiazepine metabolite, but it will not detect alprazolam and lorazepam as they are not metabolized to oxazepam. Opioid screens may not detect synthetic opioids such as fentanyl and methadone. Quantitative testing determines how much of a known drug is present and can help determine the severity of toxicity and the need for aggressive interventions (e.g., hemodialysis in ethylene glycol, methanol, and salicyclate).	**Case 5-4 (Questions 1, 7, 8)**

TOXIDROMES

1 A toxidrome is a consistent constellation of signs and symptoms associated with some specific classes of drugs. The most common toxidromes are those associated with anticholinergic activity, increased sympathetic activity, and central nervous system (CNS) stimulation or depression. Anticholinergic drugs increase heart rate and body temperature, decrease GI motility, dilate pupils, and produce drowsiness or delirium. Sympathomimetic drugs increase CNS activity, heart rate, body temperature, and blood pressure. Opioids, sedatives, hypnotics, and antidepressants depress the CNS, but the specific class of CNS depressant often cannot be easily identified.	**Case 5-4 (Questions 1, 2, 5)**

SALICYLATES

1 Acute ingestion of 150 to 300 mg/kg aspirin causes mild-to-moderate intoxication, greater than 300 mg/kg indicates severe poisoning, and greater than 500 mg/kg is potentially lethal. Symptoms of intoxication include vomiting, tinnitus, delirium, tachypnea, metabolic acidosis, respiratory alkalosis, hypokalemia, irritability, hallucinations, stupor, coma, hyperthermia, coagulopathy, and seizures. Salicylate intoxication	**Case 5-1 (Questions 1, 3),** **Case 5-2 (Questions 1–6)**

mimics other medical conditions and can be easily missed. Patients with a chronic salicylate exposure, acidosis, or CNS symptoms and those who are elderly are at high risk and should be considered for early dialysis.	
IRON	
① Acute elemental iron ingestions of less than 20 mg/kg are usually nontoxic; doses of 20 to 60 mg/kg result in mild-to-moderate toxicity, and doses of greater than 60 mg/kg are potentially fatal. Symptoms of toxicity include nausea, vomiting, diarrhea, abdominal pain, hematemesis, bloody stools, CNS depression, hypotension, and shock. Patients with severe iron poisoning do not exhibit the second stage of so-called recovery but continue to deteriorate.	**Case 5-3 (Questions 1, 2–14)**
TRICYCLIC ANTIDEPRESSANTS	
① Severe toxicity has been associated with doses of 15 to 25 mg/kg. Symptoms include tachycardia with prolongation of the PR, QTc, and QRS intervals, ST and T-wave changes, acidosis, seizures, coma, hypotension, and adult respiratory distress syndrome. A QRS segment greater than 100 milliseconds is commonly seen in severe tricyclic antidepressant overdoses.	**Case 5-4 (Questions 9–17)**
ACETAMINOPHEN	
① Toxicity is associated with acute ingestions greater than 150 mg/kg or more than 7.5 g total in adults. Symptoms in patients with toxicity include vomiting, anorexia, abdominal pain, malaise, and progression to characteristic centrilobular hepatic necrosis. Acetaminophen-induced hepatotoxicity is universal by 36 hours after ingestion, but patients who receive NAC within 8 to 10 hours after ingestion rarely exhibit hepatotoxicity. There is no consensus as to the best route of NAC administration, the optimal dosage regimen, or the optimal duration of therapy.	**Case 5-5 (Questions 1–15)**

This chapter reviews common strategies for the evaluation and management of drug overdoses and poisonings. Information for the management of specific drug overdoses is best obtained from a poison control center (reached by calling 1-800-222-1222 anywhere in the United States).

Epidemiologic Data

AMERICAN ASSOCIATION OF POISON CONTROL CENTERS AND DRUG ABUSE WARNING NETWORK

Toxicity secondary to drug and chemical exposure commonly occurs in children. The incidence of exposure to specific agents and the severity of outcomes varies based on the population studied (Table 5-1).[1–3] The number of reported toxic exposures in the United States in 2013 was approximately 2.2 million, according to the American Association of Poison Control Centers (AAPCC).[3] Approximately 70% of the reported cases were treated at home, saving millions of dollars in medical costs.

According to the Drug Abuse Warning Network, almost 5.1 million US emergency department (ED) visits involved drug misuse or abuse in the year 2011. Illicit drugs include cocaine, heroin, marijuana, ecstasy, gamma-hydroxyutyric acid, flunitrazepam (Rohypnol), ketamine, lysergic acid, phencyclidine, and hallucinogens. Of those cases, illicit drug use was mentioned more than 2.7 million times because many of the visits involved multiple drugs of abuse.[4]

AGE-SPECIFIC DATA

Stratifying patients by age can be useful in assessing the likelihood of severe toxicity from an exposure. Most unintentional ingestions by children 1 to 6 years of age occur because children are curious, becoming more mobile, and beginning to explore their surroundings, and they often put objects or substances into their mouths.[5] Severe toxicity in young children is relatively uncommon as exposures usually involve the ingestion of relatively small amounts of a single substance.[5,6] AAPCC epidemiologic data also report medication errors, which in the pediatric population commonly result from confusing units of measurement (e.g., teaspoons vs. milliliters or tablespoons vs. teaspoons), incorrect formulation or concentration administered, dispensing cup errors, and incorrect formulation or concentration dispensed from the pharmacy.[3]

In children older than 6 years of age, the reasons for toxic exposure to medications are less clear.[7] Adolescent children generally have poor knowledge of the toxicity of medications and can overdose themselves unintentionally.[5,8] The potential for suicide attempts or intentional substance abuse should not be ignored in older children. These intentional overdoses commonly involve mixed exposures to illicit drugs, prescribed medications, or ethanol and are associated with more severe toxicity and death than unintentional toxic exposures.

In geriatric patients, overdoses tend to have a greater potential for severe adverse effects compared with overdoses in other age groups.[9] Although the elderly constitute 13% of the population, they account for 33% of the drug use and 16% of the suicides.[10] Patients aged 65 or older take an average of 5.7 prescription medications along with 2 to 4 nonprescription drugs daily.[9,10] The elderly are more likely to have underlying illnesses and often have access to a variety of potentially dangerous medications. This results in higher rates of completed suicides than in other age groups.[10,11]

Information Resources

COMPUTERIZED DATABASES

A vast number of substances can be involved in a poisoning or overdose. Reliable data about the contents of products, toxicities of substances, and treatment approaches need to be readily accessible. POISINDEX, a computerized database,[11] provides information on thousands of drugs by brand name, generic name, and street name, as well as foreign drugs, chemicals, pesticides, household products, personal care items, cleaning products, poisonous insects, poisonous snakes, and poisonous plants. Annual subscriptions to POISINDEX, updated quarterly, are expensive and are generally available only in large medical centers.[12]

Table 5-1

Substances Most Commonly Involved in Poisonings[a]

Children	**Adults**	**Fatal Exposures (All Ages)**
Personal care products	Analgesics	Sedatives/hypnotics/antipsychotics
Cleaning substances	Sedatives/hypnotics/antipsychotics	Cardiovascular agents
Analgesics	Antidepressants	Opioids
Topical products	Cardiovascular agents	Stimulants
Vitamins	Cleaning substances	Alcohols, acetaminophen-containing products
Antihistamines	Alcohols	Acetaminophen
Pesticides	Pesticides	Fumes/gases/vapors
Cough and cold products	Bites, envenomations	Antidepressants
Plants	Antiepileptic agents	Antihistamines
GI products	Personal care products	Tricyclic antidepressants, aspirin
Antimicrobials	Antihistamines	Muscle relaxants
Cardiovascular	Hormones and hormone antagonists	Antiepileptic agents
Arts and office supplies	Hydrocarbons	Nonsteroidal anti-inflammatory drugs
Hormones and hormone antagonists	Antimicrobials	
Alcohols	Chemicals	
	Fumes/gases/vapors	

[a] Poisoning exposures are listed in order of frequency encountered.

GI, gastrointestinal.

PRINTED PUBLICATIONS

Textbooks and manuals also provide useful clinical information about the presentation, assessment, and treatment of toxicities. Goldfrank's Toxicologic

Emergencies[13] and the pocket-size Poisoning & Drug Overdose[14] are valuable, less-expensive alternatives to computerized database programs. Books, however, are less useful than computerized databases because information must be condensed and cannot be updated as frequently. Some drug package inserts also refer to treatment of acute toxicities; however, the information can be inadequate or inappropriate.[15,16]

POISON CONTROL CENTERS

Poison control centers provide the most cost-effective and accurate information to health care providers and to the general public.[17,18] Poison centers are staffed by trained poison information specialists who have a pharmacy, nursing, or medical background. Physician backup is provided 24 hours a day by board-certified medical toxicologists. The nonphysician clinical toxicologists, pharmacists, and nurses who staff poison control centers are certified as specialists in poison information by the AAPCC or as clinical toxicologists by the American Board of Applied Toxicology.[19]

The poison information specialist must accurately and efficiently assess event-specific toxicity by telephone, without the benefit of direct observation of the patient. The specialist must communicate this assessment along with treatment information quickly, accurately, and professionally in a reassuring manner. Subsequent to telephone consultations, poison control center staff should initiate follow-up calls to determine the effectiveness of the recommended treatment and the need for additional evaluation or treatment.[20,21]

EFFECTIVE COMMUNICATION

Effective communication is essential to the assessment of potential poisonings. In most situations, the person seeking guidance on the management of a potentially toxic exposure is the parent of a small child who may have ingested a substance. The caller is usually anxious about the child and may feel guilty about the exposure. To calm the caller, the health care provider should quickly reassure the individual that telephoning for help was appropriate and that the best assistance possible will be provided.[21] If English is not the first language of the caller, or if there are other communication barriers (e.g., panic), solutions must be found to enhance outcomes. Most poison centers subscribe to translation services or have bilingual staff to communicate with non–English-speaking callers. Poison centers also have special equipment to serve the hearing- and speech-impaired populations.

Once calm, effective communication is established, the health care provider should first determine whether the patient is conscious and breathing and has a pulse. If life-threatening symptoms have occurred, the caller should call 9-1-1 for emergency services. If the health care provider does not have the knowledge or resources to provide poison information, he or she should refer the caller to the closest poison control center. Information on the location and phone number of the nearest poison control center can be found at http://www.aapcc.org or by calling 1-800-222-1222 in the United States.

GENERAL MANAGEMENT

Supportive Care and "ABCs"

Management of poisoned or overdosed patients is primarily based on symptomatic and supportive care. Specific antidotes exist only for a small percentage of the thousands of potential drugs and chemicals that can cause a poisoning.

The first aspect of patient management should always be basic support of airway, breathing, and circulation (the "ABCs"). The assessment and treatment of the potentially poisoned patient can be separated into seven primary functions: (a) gathering history of exposure, (b) evaluating clinical presentation (i.e., "toxidromes"), (c) evaluating clinical laboratory patient data, (d) removing the toxic source (e.g., irrigating eyes, decontaminating exposed skin), (e) considering antidotes and specific treatment, (f) enhancing systemic clearance, and (g) monitoring outcome.[22–24]

GATHERING HISTORY OF EXPOSURE

Comprehensive historical information about the toxic exposure should be gathered from as many different sources as possible (e.g., patient, family, friends, prehospital health care providers). This information should be compared for consistency and evaluated relative to clinical findings and laboratory results. The patient's history of the exposure is often inaccurate and should be confirmed with objective findings.[22,23,25] For example, a patient who presents to an ED with a supposed hydrocodone and carisoprodol overdose is expected to be lethargic or comatose. If the patient arrives wide awake with tachycardia and agitation, the clinician should suspect exposure to other substances.

Specific information should be sought concerning the patient's state of consciousness, symptoms, probable intoxicant(s), and maximal amount and dosage form(s) of substance ingested, as well as when the exposure occurred. Medications, allergies, and prior medical problems also should be ascertained to facilitate development of treatment plans (e.g., a history of renal failure may indicate the need for hemodialysis to compensate for decreased renal drug clearance).[22,23]

EVALUATING CLINICAL PRESENTATION AND TOXIDROMES

A thorough physical examination is needed to characterize the signs and symptoms of overdose, and it should be conducted serially to determine the evolution or resolution of the patient's intoxication. An evaluation of the presenting signs and symptoms can provide clues to the drug class causing the toxicity, confirm the historical data surrounding the toxic exposure, and suggest initial treatment.[22,26–28] The patient may be asymptomatic on presentation, even though a potentially severe exposure has occurred, if absorption of the drug or toxic substance is incomplete or if the substance has not yet been metabolized to a toxic substance.[29–31]

Characteristic toxidromes (i.e., a constellation of signs and symptoms consistent with a syndrome) can be associated with some specific classes of drugs.[23,27,28] The most common toxidromes are those associated with anticholinergic activity, increased sympathetic activity, and central nervous system (CNS) stimulation or depression. Anticholinergic drugs can increase heart rate and body temperature, decrease gastrointestinal (GI) motility, dilate pupils, and produce drowsiness or delirium. Sympathomimetic drugs can increase CNS activity, heart rate, body temperature, and blood pressure (BP). Opioids, sedatives, hypnotics, and antidepressants can depress the CNS, but the specific class of CNS depressant often cannot be easily identified.

Classic findings may not be present for all drugs within a therapeutic class. For example, opioids generally induce miosis, but

---

meperidine can produce mydriasis. Furthermore, the association of symptoms with a particular class of toxic substances is difficult when more than one substance has been ingested. Practitioners should not focus only on the specific clinical findings associated with a toxidrome. Rather, they should consider all subjective and objective data gathered from the history of exposure, the patient's medical history, physical examination, and laboratory findings.[27]

INTERPRETATION OF LABORATORY DATA

Drug Screens

A urine drug screen can be useful in identifying the presence of drugs and their metabolites in selected patients but is not indicated in all cases of drug overdose. Urine drug screens can be useful in a patient with coma of unknown etiology, when the presented history is inconsistent with clinical findings, or when more than one drug might have been ingested.[32,33]

Pharmacokinetic Considerations

The absorption, distribution, metabolism, and elimination of drugs in the overdosed patient can be quite different than when the drug is taken in usual therapeutic doses.[29–31] The expected pharmacodynamic and pharmacokinetic features of drugs can be substantially altered by large drug overdoses, especially with drugs that exhibit dose-dependent pharmacokinetics. The rate of drug absorption is generally slowed by large overdoses, and the time to reach peak serum drug concentrations can be delayed.[32,34] For example, peak serum concentrations of phenytoin can be delayed for 2 to 7 days after an orally ingested overdose.[35,36] The volume of distribution of an overdosed drug can be increased, and when usual metabolic pathways become saturated, secondary clearance pathways can be important. For example, large overdoses of acetaminophen saturate glutathione mechanisms of metabolism, resulting in hepatotoxicity.[37]

When the pharmacokinetic parameters of an overdosed drug are altered, serial plasma concentration measurements can better define the absorption, distribution, and clearance phases of the ingested substance. Pharmacokinetic parameters that have been derived from therapeutic doses should not be used to predict whether absorption is complete or to predict the expected duration of intoxication caused by large overdoses.[31,38,39]

DECONTAMINATION

After the airway and the cardiopulmonary system are supported, efforts should be directed toward removing the toxic substance from the patient (i.e., decontamination).[22,40] Decontamination presumes that both the dose and the duration of toxin exposure are important in determining the extent of toxicity and that prevention of continued exposure will decrease toxicity.[29–31,40] This intuitive concept is clearly relevant to ocular, dermal, and respiratory exposures, when local tissue damage is the primary problem. Respiratory decontamination involves removing the patient from the toxic environment and providing fresh air or oxygen to the patient. Decontamination of skin and eyes involves flushing the affected area with large volumes of water or saline to physically remove the toxic substance from the surface.[22,23]

Gastrointestinal Decontamination

Because most poisonings and overdoses result from oral ingestions, measures to decrease or prevent continued GI absorption have commonly been used to limit the extent of exposure.[22,23,37] GI decontamination should be considered if the ingestion is large enough to produce potentially significant toxicity, or if the potential severity of the ingestion is unknown and the time since ingestion is less than 1 hour. The following methods have historically been used: (a) evacuation of gastric contents by emesis or gastric lavage, (b) administration of activated charcoal as an adsorbent to bind the toxic substance remaining in the GI tract, (c) use of cathartics or whole bowel irrigation (WBI) to increase the rectal elimination of unabsorbed drug, or (d) a combination of any of these methods.[41–46]

The efficacy of GI decontamination varies, depending on when the process is initiated relative to the time of ingestion, dose ingested, and other factors. Furthermore, ipecac-induced emesis, gastric lavage, cathartics, and activated charcoal are not directly associated with improved patient outcomes.[41–46]

The most appropriate method for GI tract decontamination remains unclear because sound comparative data for different methods of GI decontamination are not available. Clinical research in healthy subjects, by necessity, must use nontoxic doses of drugs. Studies using nontoxic doses are not applicable to the overdose situation because alterations in GI absorption can occur with large doses. In addition, low-dose studies generally rely on pharmacokinetic end points such as peak plasma concentrations, area under the plasma concentration–time curve, or quantity of drug recovered from the urine.[41,42,44–46] In contrast, clinical studies of GI decontamination methods in patients who have ingested toxic doses of a substance use clinical outcomes or a directional change in serum drug concentrations.[41,42,45,46] These latter trials are not standardized with respect to the dose ingested or to the time interval between drug ingestion and GI decontamination.[41–46]

Ipecac-Induced Emesis and Gastric Lavage

Ipecac-induced emesis and gastric lavage primarily remove substances from the stomach. Their efficacy is affected significantly by the time the ingested substance remains in the stomach. Gastric lavage and ipecac-induced emesis are most effective when implemented before the substance moves past the stomach into the intestine (usually within 1 hour).[41,42]

The commonly used adult gastric lavage tube (36F) has an internal diameter too small to allow recovery of large tablet or capsule fragments. An even smaller diameter lavage tube is used for children.[42] Gastric lavage may be useful only if large amounts of a liquid substance were ingested and the patient arrived within 1 hour of the ingestion.[45] However, patients usually arrive in the ED more than an hour after ingestion, when absorption of the toxin has most likely already occurred. As a result, the efficacy of these procedures in overdose situations is minimal, and no studies have confirmed that use of gastric lavage or ipecac-induced emesis improves the outcome of the patient.[41,42,47] For these reasons, ipecac is no longer used, and gastric lavage is used only in rare, specific situations.

Activated Charcoal

In 1963, a review article concluded that activated charcoal was the most valuable agent available for the treatment of poisoning.[48] This conclusion was based only on studies in fasting patients who had nontoxic exposures. Nevertheless, data from those studies were extrapolated to poisoned patients. Since then, activated charcoal has become the preferred method of GI decontamination for the treatment of toxic ingestions.[22,40,48]

The goal of the therapy is to decrease the absorption of the substance and reduce or prevent systemic toxicity.[43] Unfortunately, there are no satisfactorily designed clinical studies assessing benefit from the use of activated charcoal to guide the use of this therapy. There is also no evidence that the administration of activated charcoal improves clinical outcomes.[43]

The use of activated charcoal at a dose of 1 g/kg should be considered when the patient has ingested a toxic substance that is known to be absorbed by activated charcoal within 1 hour of the ingestion. The potential for benefit is unknown if the activated charcoal is given more than 1 hour after ingestion.[43] It should be noted that iron and lithium are not absorbed by activated charcoal. Other forms of GI decontamination must be used to remove those substances from the GI tract.[43]

Generally the use of activated charcoal is safe. Although there are relatively few reports of adverse effects from the use of activated charcoal, there are numerous reports of complications, usually involving aspiration. It is essential that the patient has an intact or protected airway (intubation) before activated charcoal is administered, especially in drowsy patients or patients who may rapidly become obtunded.[43]

Vomiting with aspiration of activated charcoal occurs in about 5% of patients who receive activated charcoal.[43,49–51] The resulting pulmonary problems can be caused by aspiration of acidic stomach contents or the charcoal. Decreased oxygenation can occur immediately, or pulmonary effects can occur later.[51–55] Adult respiratory distress syndrome has resulted after the unintentional instillation of charcoal into the lung.[51] Aspiration of charcoal can result in chronic lung disease or fatalities, whereas the toxic exposure, for which the charcoal was administered, is often not lethal or even serious.[52,56]

Cathartics

Historically, sorbitol (a cathartic) was often administered with activated charcoal to enhance passage of the charcoal–substance complex through the GI tract. However, decreased transit time through the bowel has not been proven to decrease absorption because drug absorption does not take place in the large bowel.[44] Sorbitol is also associated with vomiting and aspiration.[44] Hypernatremia can also develop subsequent to the administration of repeat doses of activated charcoal with sorbitol.[57,58] Currently, most EDs use aqueous activated charcoal mixtures rather than charcoal–sorbitol combinations. Because cathartics are not effective in reducing drug absorption or increasing patient outcome, their use is no longer advised.[44]

Whole Bowel Irrigation

WBI with a polyethylene glycol–balanced electrolyte solution (e.g., Colyte, GoLYTELY) can successfully remove substances from the entire GI tract in a period of several hours. WBI is effective with ingestions of sustained-release dosage forms, as well as substances that form bezoars (concretions of tablets or capsules), such as ferrous sulfate or phenytoin.[23,45,59] WBI is also indicated when the toxic agent is not adsorbed by activated charcoal (e.g., body-packer packets, lithium, iron, potassium).[22,23,45,59] This method of GI decontamination takes much longer to complete and is associated with poor patient compliance because large volumes of fluid (2 L/hour for adults until the effluent is clear) need to be ingested to be effective.[59] A nasogastric (NG) tube can be inserted, and the WBI fluid can be administered via NG tube so that lack of patient compliance is no longer a factor.[45]

ANTIDOTES AND SPECIFIC TREATMENTS

An antidote is a drug that neutralizes or reverses the toxicity of another substance. Some antidotes can displace a drug from receptor sites (e.g., naloxone for opioids, flumazenil for benzodiazepines), and some can inhibit the formation of toxic metabolites (e.g., N-acetylcysteine [NAC] for acetaminophen, fomepizole for methanol).[23,60,61] Some treatments are highly effective for the management of individual drug overdoses but do not meet the definition of an antidote. For example, sodium bicarbonate is used to treat the cardiotoxicity arising from tricyclic antidepressant (TCA) overdoses, and benzodiazepines are used to treat CNS toxicity associated with cocaine and amphetamine overdoses.[62–64] However, it is important to note that for antidotes to be effective, they must be readily available at the health care facility in adequate doses to treat the patient in a timely manner.[65]

ENHANCING SYSTEMIC CLEARANCE

Hemodialysis and manipulation of urine pH can enhance the clearance of substances. Hemodialysis can successfully treat some specific intoxications (e.g., methanol, ethylene glycol, aspirin, theophylline, lithium). Hemodialysis can also be used in patients with severe acid–base disturbances or renal dysfunction.[47] Alkalinization of the urine can enhance the elimination of drugs such as aspirin and phenobarbital.[66–68]

MONITORING OUTCOME

Selecting the appropriate parameters and length of time to monitor a patient who has been exposed to a toxic agent requires knowledge of toxic effects and the time course of the intoxication.[33,34] Most patients who are at risk for moderate or severe toxicity should be monitored in an intensive care unit (ICU) with careful assessments of cardiac, pulmonary, and CNS function.[69,70]

ASSESSMENT OF SALICYLATE INGESTION

Gathering a History

CASE 5-1

QUESTION 1: A.J., the mother of a 3-year-old child, states that her son, R.J., has ingested some aspirin tablets. What additional information should be obtained from or given to A.J. at this time?

Obtaining an initial assessment of the patient’s status is essential. The caller’s telephone number should be obtained in the event that the call is disconnected, initial recommendations need to be modified, or subsequent follow-up is needed. The health care provider should ask for patient-specific information with questions that are nonthreatening and nonjudgmental. The caller should be reassured that calling for help was the right thing to do.

Evaluating Clinical Presentation

CASE 5-1, QUESTION 2: On further questioning, A.J. states that R.J. is crying and complaining of a stomachache. Otherwise, the child appears to be acting normally. R.J. was found sitting on the bedroom floor with an aspirin bottle in his hand and some partially chewed tablets on the floor next to him. A.J. states that the child had the same look on his face that he has when he eats things that he does not like. A.J. reports that she can see white tablet material gummed on the child's teeth. The mother was gone no more than 5 minutes and had asked her 5- and 6-year-old sons to watch their brother. What additional information is needed to correctly assess the potential for toxicity in R.J.?

To determine the potential toxicity for an unintentional ingestion, it is important to assess the presence of symptoms and to identify the substance ingested. Inquiries should begin with open-ended questions to determine the facts that the caller is certain of versus what may have been assumed. The answers usually point to more specific information that is needed to accurately assess the exposure.[20]

R.J's symptoms presently are not life-threatening. His behavior is consistent with being scared in response to the mother's anxiety. Once it has been established that the child does not need immediate life-saving treatment, the caller is generally more willing and able to answer additional questions.

A.J. already has provided information about the child's symptoms. More information is needed to determine the identity of the ingested substance, the time of ingestion, the brand of aspirin (to ensure that the product is not an aspirin-combination or even an aspirin-free formulation), the dosage form, the number of dosage

units in a full container, and the number of remaining dosage units in the container. The parent should be advised to look for tablets under beds, rugs, or other locations out of sight (e.g., wastepaper baskets, toilets, pet food dishes, pockets). The dosage forms in the container should be identical in appearance, and the contents should be what are stated on the label. Information concerning the child's weight and health status, as well as whether the child is taking other medications, is also important. The child's weight is useful in determining the maximum milligram per kilogram dose of aspirin that was ingested.

When more than one child is present during an ingestion, the caller should be questioned as to whether other children also could have participated in the ingestion.

In this situation, the children could have shared equally in the missing medication, all of the drug could have been fed to one child, or all of the drug could have been ingested by the oldest or most aggressive child. When it is unclear how much is missing among a group of children, each child should be evaluated and managed as if he or she may have ingested the total missing quantity.

Triage of Call

CASE 5-1, QUESTION 3: A.J. has now determined that a total of seven tablets each containing 81 mg per tablet of aspirin are missing from the bottle. Because A.J. recalls having taken two aspirin tablets from this bottle, it is not likely that her son took more than seven tablets. A.J. states that R.J. weighs 42 pounds. What treatment is needed for this child?

The maximal dose of aspirin ingested by this child is likely to be much less than the minimal dose required to cause significant symptoms based on his weight for his age (i.e., 42 pounds or approximately 19 kg). A dose of 150 mg/kg of aspirin is the smallest dose at which treatment or assessment at a health care facility is necessary.[68,71] A.J. is likely to have ingested a maximum of 567 mg of aspirin (i.e., seven 81-mg tablets), which is about 29.8 mg/kg (567 mg divided by 19 kg). If this child is healthy, takes no medications, and is not allergic to aspirin, the child does not require any treatment. With this history of ingestion, the only adverse effect that might occur is some mild nausea. Providing information to the mother that her child had not ingested a toxic or dangerous amount will be reassuring.

For many years, aspirin was the most common cause of unintentional poisoning and poisoning deaths among children.[71–73] However, safety closure packaging and reduction of the total aspirin content in a full bottle of children's aspirin to approximately 3 g has steadily reduced the frequency of pediatric aspirin poisoning and deaths.[72–74] Although acute aspirin poisoning remains a problem, the largest percentage of life-threatening intoxications now results from therapeutic overdose.[68] Therapeutic overdoses occur when a dose is given too frequently, when both parents unknowingly dose the child with the drug, or when too large a dose is given. Therapeutic overdoses are especially problematic when excessive doses are given for a prolonged period and the drug is able to accumulate.[68]

Outcome for A.J.

Follow-up telephone consultation on toxic ingestions is important to identify children who unexpectedly develop symptoms that might need to be treated. A telephone call to A.J. 6 to 24 hours after her initial call would be appropriate to follow up on the child. On a call back to A.J., the parent stated that she gave R.J. lunch at the appropriate time. R.J. then watched cartoons, took his usual nap, and remained asymptomatic.

Acute and Chronic Salicylism

SIGNS AND SYMPTOMS

CASE 5-2

QUESTION 1: A.S., a 71-year-old, 59-kg woman with a history of chronic headaches, has taken 10 to 12 aspirin tablets daily for several months. On the evening of admission, she became lethargic, disoriented, and combative. Additional history revealed that she ingested up to 95 aspirin tablets on the morning of admission (about 11 hours earlier) in a suicide attempt. She complained of ringing in her ears, nausea, and two episodes of vomiting. She is disoriented and lethargic. Vital signs were BP 148/95 mm Hg, pulse 114 beats/minute, respirations 38 breaths/minute, and temperature 101.2°F. A.S.'s laboratory data obtained on admission were as follows:

Serum sodium (Na), 144 mEq/L
Potassium (K), 2.5 mEq/L
Chloride (Cl), 103 mEq/L
Bicarbonate, 9 mEq/L
Glucose, 58 mg/dL
Blood urea nitrogen (BUN), 38 mg/dL
Creatinine, 2.5 mg/dL

Arterial blood gas (ABG) values (room air) were as follows: pH, 7.14; PCO_2, 18 mm Hg; and PO_2, 96 mm Hg. A serum salicylate concentration measured approximately 12 hours after the acute ingestion was 90 mg/dL. Her hemoglobin was 9.6 g/dL with a hematocrit of 28.9% and a prothrombin time (PT) of 16.4 seconds. Is A.S. at high risk because of her ingestion?

The symptoms and severity of salicylate intoxication depend on the dose consumed; the patient's age; and whether the ingestion was acute, chronic, or a combination of the two.[73,75,76] This case illustrates an acute ingestion in someone who has also chronically ingested aspirin. Acute ingestion of 150 to 300 mg/kg of aspirin is likely to produce mild-to-moderate intoxication, greater than 300 mg/kg indicates severe poisoning, and greater than 500 mg/kg is potentially lethal.[68,71] A.S., who ingested approximately 523 mg/kg, has taken a potentially lethal dose. Chronic salicylate intoxication is usually associated with ingestion of greater than 100 mg/kg/day for more than 2 days.[68,71] A.S. has been taking 66 mg/kg/day for her headaches in addition to her acute ingestion. A.S. demonstrates many of the findings typical of severe acute salicylism (see Pathophysiology of Salicylate Intoxication and Assessment of Toxicity sections). A.S.'s prognosis is potentially poor because she is elderly and has taken a potentially lethal overdose of aspirin.

Pathophysiology of Salicylate Intoxication

CASE 5-2, QUESTION 2: Describe the pathophysiology and clinical features of acute and chronic salicylism.

Toxicity from salicylate exposure results in direct irritation of the GI tract, direct stimulation of the CNS respiratory center, stimulation of the metabolic rate, lipid and carbohydrate metabolism disturbances, and interference with hemostasis.[68,71,73,75,76] Toxic doses of salicylate directly stimulate the medullary respiratory center leading to nausea, vomiting, tinnitus, delirium, tachypnea, seizures, and coma and influence several key metabolic pathways.[68,73–77] Direct stimulation of the respiratory drive increases the rate and depth of ventilation, which can result in primary respiratory alkalosis. The respiratory alkalosis causes increased renal excretion of bicarbonate, resulting in decreased

---

buffering capacity. The patient usually presents with a partially compensated respiratory alkalosis.[68,74,75,77] Hypokalemia can result from increased GI and renal losses of potassium, as well as from systemic alkalosis.[68,75,76] Although marked metabolic and neurologic abnormalities are most commonly observed in young children with advanced salicylate intoxication, adolescents or adults acutely poisoned with a large dose of salicylates can exhibit these symptoms as well.[68,74,75] Acute salicylism in a young child often takes a more severe course than that typically seen in adults. After acute ingestion, children quickly pass through the phase of pure respiratory alkalosis. Renal bicarbonate loss secondary to respiratory alkalosis reduces the buffering capacity more profoundly in a child and facilitates the development of metabolic acidosis.[68,73,75,77]

Salicylates have toxic effects on several biochemical pathways that contribute to metabolic acidosis and other symptoms.[68,75,77] Mitochondrial oxidative phosphorylation is uncoupled and results in an impaired ability to generate high-energy phosphates, increased oxygen use and carbon dioxide production, increased heat production and hyperpyrexia, increased tissue glycolysis, and increased peripheral demand for glucose. Salicylates also inhibit key dehydrogenase enzymes within the Krebs cycle, resulting in increased levels of pyruvate and lactate. The increased demand for peripheral glucose causes increased glycogenolysis, gluconeogenesis, lipolysis, and free fatty acid metabolism. The latter results in enhanced formation of keto acids and ketoacidosis.[73,77]

The patient may become severely volume depleted through several mechanisms.[68,75,77] Hyperthermia and hyperventilation produce increased insensible water loss, vomiting may promote GI fluid losses, and the solute load caused by altered glucose metabolism results in an osmotic diuresis. Depending on the patient’s acid–base balance and net fluid and electrolyte intake and output, serum sodium and potassium concentrations may be normal, elevated, or decreased. Hypernatremia and hypokalemia are most common.[73,75]

Blood glucose concentration is usually normal or slightly elevated, although hypoglycemia may accompany chronic salicylism (e.g., as illustrated by A.S.) or occur late in acute intoxication. CNS glucose levels can be markedly reduced in the presence of normal blood glucose concentrations because increased CNS glucose utilization to generate high-energy phosphate exceeds the rate at which glucose can be supplied.[68,73,75,77]

ASSESSMENT OF TOXICITY

CASE 5-2, QUESTION 3: What signs, symptoms, and laboratory values in A.S. are consistent with salicylate intoxication?

A.S. demonstrates many of the findings typical of severe acute salicylism. Hyperventilation has resulted from the direct respiratory stimulant effects of salicylate and as compensation for her metabolic acidosis (P_{CO_2}, 18 mm Hg; pH, 7.14; serum bicarbonate, 9 mEq/L; respiratory rate, 38 breaths/minute). Hypokalemia (2.8 mEq/L) in the presence of metabolic acidosis represents severe potassium depletion because of increased renal and possibly GI losses. Hyperpyrexia caused by salicylate is present in A.S., although an infectious cause must also be considered. Her neurologic symptoms of lethargy, disorientation, and combativeness, as well as tinnitus, nausea, and vomiting, are commonly seen in severe salicylate intoxication. In addition, being elderly and taking a lethal amount of aspirin bodes ill for this patient’s outcome.

LABORATORY EVALUATION

CASE 5-2, QUESTION 4: What objective evaluations should be assessed in a patient with presumed salicylate intoxication?

A.S.’s workup illustrates a thorough initial patient evaluation. Laboratory evaluation should include ABG values, serum electrolytes, BUN, serum creatinine, blood glucose, and a complete blood cell count.[73,74] Urine should be tested for specific gravity and pH.[73] In symptomatic patients, a PT or international normalized ratio (INR) and partial thromboplastin times are useful to assess the presence of salicylate-induced coagulopathy. Vitals signs should be monitored for an increased respiratory rate and hyperpyrexia.[74,75] Physical examination should include an evaluation of chest radiograph, cardiopulmonary and neurologic function, and measurement of urine output.[75]

A salicylate blood concentration should be obtained immediately and every 2 hours in patients.[24,64,73,75] Serum salicylate concentrations should be reassessed every 2 hours to verify that the original concentration represented a peak level and that the salicylate level is decreasing rather than increasing.[24,68,73,76,78] Obtaining the units of measurement on salicylate serum concentrations is essential because different laboratories report concentrations in different units (e.g., mg/dL, mcg/mL, mmol/L). An incorrect interpretation of the salicylate unit of measurement can result in overestimates or underestimates of the severity.[24]

Manifestations of severe acute salicylism include a variety of neurologic signs and symptoms: disorientation, irritability, hallucinations, lethargy, stupor, coma, and seizures.[69,73] Hyperthermia may be marked and can result in the inappropriate administration of aspirin as an antipyretic. Coagulopathy can occur because of impaired platelet function, hypoprothrombinemia, reduced factor VII production, and increased capillary fragility, especially when aspirin is taken chronically.[75–77] Pulmonary edema and acute renal failure also can occur, but the former occurs more commonly after chronic intoxication.[75,77,78]

Chronic salicylism symptoms are similar to acute intoxications. However, patients with chronic exposures may have fewer GI symptoms, but they generally appear more ill and have more CNS symptoms.[71,79] In both adults and children, the principal signs of chronic salicylism are a partially compensated metabolic acidosis, increased anion gap, ketosis, dehydration, electrolyte loss, hyperventilation, tremors, agitation, confusion, stupor, memory deficits, renal failure, and seizures.[73,75,76,80] The severity of CNS manifestations is related to the cerebrospinal fluid (CSF) salicylate concentration.[74,75] CSF concentrations may increase in the presence of systemic acidosis because a greater fraction of salicylate is not ionized and can cross the blood–brain barrier. Therefore, metabolic acidosis is especially dangerous in a salicylate-intoxicated patient.[73,75]

Unless the history of salicylate intake is specifically sought, the problem may not be immediately apparent, especially in the elderly in whom such findings are likely to be attributed to other causes (e.g., encephalitis, meningitis, diabetic ketoacidosis, myocardial infarction).[24,75,79] Delay in diagnosis has been associated with increased mortality.[24,68,75,79] Unfortunately, plasma salicylate concentrations do not correlate well with the degree of poisoning in chronically intoxicated patients. It is more important to treat the patient according to the clinical status rather than his or her salicylate concentration.[71] Death in patients with salicylism, whether acute or chronic, results from CNS or cardiac dysfunction, or pulmonary edema.[73,75,79]

MANAGEMENT

CASE 5-2, QUESTION 5: What would be a reasonable management plan for A.S.?

Management of salicylate intoxication depends on the degree of acid–base and electrolyte disturbances.[68,73,75] Activated charcoal is not indicated for A.S. because the ingestion occurred

---

approximately 10 hours ago and she has a somewhat altered mental status.[46] The risk of aspiration is greater than the value of possibly adsorbing any remaining aspirin from the GI tract. In addition, A.S. already has symptoms of salicylate poisoning, indicating that the aspirin has already been absorbed. Others might argue that if she ingested 95 tablets, some of the drug may still be present in the GI tract and giving activated charcoal late may bind some of the drug still present. The benefit versus risk of giving activated charcoal must be assessed. A.S.'s hypokalemia, acidosis, and hypoglycemia must be corrected, and it is probably best accomplished through the administration of intravenous (IV) hypotonic saline–dextrose solutions combined with potassium supplementation. This solution is administered at a rate that replaces the patient's deficits and keeps pace with continued losses.[68,73,75–77] Care should be taken to avoid overzealous fluid therapy, which can predispose the patient to cerebral or pulmonary edema.[73,77] Administration of an IV dextrose bolus is also indicated because A.S. is hypoglycemic (60 mg/dL).[73,75–77]

Sodium Bicarbonate

It is important to correct A.S.'s acidosis because acidosis will increase CSF salicylate concentrations.[74,75] Correction of acidosis can be accomplished by adding sodium bicarbonate to her IV fluids.[68,73–76] A.S.'s serum sodium and potassium concentrations should be monitored closely as adding potassium to IV fluids will mostly likely be required.[82] Providing adequate ventilation to prevent respiratory alkalosis is essential. With a respiratory rate of 36 breaths/minute, placing the patient on a ventilator to assist with breathing might be considered. However, forced mechanical ventilation can interfere with the patient's need to compensate to maintain the serum pH. Patients on ventilators can become severely acidotic, which can result in death because of an inability to compensate adequately.[73,83]

Seizures

Seizures are not evident in A.S. but can be encountered in cases of severe salicylate poisoning. Seizures generally carry a poor prognosis and are indicative of severe salicylate intoxication that requires hemodialysis.[73] Other treatable causes of seizures (e.g., marked alkalosis, hypoglycemia, hyponatremia) can be present in individuals such as A.S. and should be ruled out. If seizures occur, benzodiazepines are the drugs of choice for treatment.[73]

Coagulopathy and Hyperthermia

Coagulopathy generally responds to vitamin K_1, which should be given if the PT or INR is prolonged.[73] GI bleeding or other hemorrhage can occur, but it is not common.[73,75,76] Mild hyperthermia usually does not require therapy, but cooling fans and mist may be required for extremely elevated temperatures.[73,77]

Pulmonary Edema

Noncardiogenic pulmonary edema commonly occurs in salicylate intoxications, especially when the overdose is attributable to chronic ingestions.[73,75,78] Pulmonary edema is associated with a high incidence of neurologic symptoms in patients and can occur even without fluid overload.[75,78] Increased alveolar capillary membrane permeability, prostaglandin effects, and a metabolic interaction with platelets releasing membrane permeability substances are the primary mechanisms for the cause of pulmonary edema associated with salicylate overdose. Treatment is aimed at reducing salicylate levels via alkalinization or hemodialysis.[78]

Alkalinization

CASE 5-2, QUESTION 6: What measures will enhance salicylate elimination? Which of these may be indicated in A.S.?

Alkalinization of the urine and hemodialysis can enhance the excretion of salicylate in overdose situations.[68,74] Hemodialysis is preferred because it can also correct fluid and electrolyte imbalances.[75,78,79] Sodium bicarbonate is recommended for alkalinization to increase the arterial pH with the goal of minimizing salicylate transport into the CNS.[74,75,77]

Although large doses of sodium bicarbonate can enhance the renal elimination of the weak acid and shorten its half-life, this treatment does not favorably influence the morbidity or mortality of patients with salicylism. Alkalinization with forced fluid diuresis can also place the patient at risk for sodium and fluid retention, as well as pulmonary edema if too much fluid is given too quickly.[76,78,79,81] Whether the urine can be adequately alkalinized (pH >7) in severely intoxicated pediatric patients has been questioned because of the large acid load that is excreted.[68,73,74] Nevertheless, urine alkalinization with sodium bicarbonate should be attempted in severely salicylate-intoxicated adult patients such as A.S.

Potassium replacement in patients receiving alkalinization is essential.[73,75,77] These patients may require large amounts of potassium supplementation as a result of renal wasting of potassium. The risk for pulmonary edema can be minimized if this is done without forcing fluids.[73,75–77]

Hemodialysis should be considered in patients who show progression of severe salicylate intoxication and seizure activity, renal failure, or plasma salicylate concentrations in the potentially fatal range.[68,75,76,78,80] Patients with a chronic exposure, acidosis, or CNS symptoms and those who are elderly or ill are high-risk patients and should be considered for early dialysis.[75,80] Because A.S. has many of the risk factors, she is a candidate for emergent hemodialysis.

CLINICAL OUTCOME OF PATIENT A.S.

A repeat salicylate level 6 hours later (18 hours after ingestion) had increased to 95 mg/dL. Her chemistry panel revealed serum sodium, 143 mEq/L; potassium, 2.2 mEq/L; chloride, 99 mEq/L; bicarbonate, 8mEq/L; glucose, 77 mg/dL; creatinine, 4.9

mg/dL; and BUN, 43mg/dL. Her hemoglobin was now 8.4 g/dL with a hematocrit of 23% and a PT of 16.6 seconds. A.S.'s pH on blood gases remained in the 7.2 to 7.3 range. Urinary alkalinization was attempted with a high-dose IV sodium bicarbonate infusion in an attempt to reach a urine pH of 7.5. However, her urine pH never increased above pH 5.7. A.S. became fluid overloaded and exhibited dyspnea. She was placed on a ventilator with worsening of her symptoms. A chest radiograph showed pulmonary edema. A.S. became confused and agitated, pulling at her IV lines and trying to get out of bed. Nephrology was consulted to provide emergent hemodialysis to correct the acidosis, electrolyte abnormalities, and fluid overload. As the catheter was being placed, the patient had a tonic–clonic seizure. Lorazepam 2 mg IV was administered and the seizure stopped. At this time, the patient was unresponsive. She had another tonic–clonic seizure, went into respiratory arrest, coded, and could not be resuscitated.

ASSESSMENT OF IRON INGESTION

Gathering History and Communications

CASE 5-3

QUESTION 1: The babysitter of K.M., a 21-month-old girl, calls the ED because the child is vomiting and appears to have been playing with an open, unlabeled bottle of green tablets. The child was left alone in her room for about 20 minutes to take a nap. Why might the consultation with this babysitter be expected to be more difficult than the consultation in Case 5-1, Question 1?

In cases of unintentional pediatric ingestions, phone calls to a health care provider, a health care facility, or a poison control center made by individuals other than the parent are usually more difficult to manage as the caller is often unable to provide all patient-specific information needed (e.g., patient weight, chronic medications) to accurately assess the drug ingestion. Additional information is often needed from a parent. Nonparent callers also tend to be more upset about an unintentional ingestion and may have more difficulty than a parent in taking decisive action.

Triage of Call

CASE 5-3, QUESTION 2: Despite additional questioning, K.M.'s babysitter cannot identify the tablets. K.M. is still vomiting, and the vomitus is green like the color of the tablets. According to the babysitter, K.M. is the child of a single mother who is not known to have flu or any GI illness at this time. The child's mother is currently at work and is not answering her cell phone. What recommendations could be provided to K.M.'s babysitter at this time?

With this history, the practitioner should consider whether the information presented by K.M.'s babysitter is consistent with a drug ingestion and whether this incident is likely to be associated with a significant adverse outcome. Most 2-year-old children experience limited toxicity with unintentional drug ingestions because the amount of substance actually ingested is usually small.[5,6] Nevertheless, some substances (e.g., methanol, ethylene glycol, nicotine, caustic substances, camphor, chloroquine, clonidine, diphenoxylate-atropine, theophylline, oral hypoglycemic agents, calcium-channel blockers, TCAs, opioids) can produce significant toxicity even when small amounts are ingested.[6,84,85]

Although the history of drug ingestion in K.M. is somewhat vague, the description of green tablets and green-colored vomitus suggest possible ingestion of iron tablets. Because this is a possible exposure with a realistic potential for severe toxicity, K.M. should be brought to the ED for evaluation. Depending on the distance to the hospital and the anxiety level of the babysitter, the practitioner might want to instruct the babysitter to call for an ambulance. She should be instructed to bring the green tablets to the ED along with the child so the tablets can be identified. Other medications in the house should also be brought to the ED, and the mother should be contacted.

Substance Identification

CASE 5-3, QUESTION 3: K.M.'s mother has been reached and confirmed that the only green tablets in the house are her iron supplements. The babysitter was instructed to bring K.M. to the nearest Emergency Department, and the mother will meet them there. On arrival K.M. is still vomiting but is fully awake and alert with a heart rate of 122 beats/minute, a respiratory rate of 26 breaths/minute, a rectal temperature of 98.9°F, and pulse oximetry of 100%. How can the maximal potential severity of this ingestion be estimated at this time?

K.M.'s vital signs, when corrected for age, are normal. Attention should now focus on identifying the ingested substance and the maximal potential severity of the ingestion. Although this case involves an unknown ingestion, with a possibility of being a severe case of iron intoxication, the identity of the tablets still has not been verified. Therefore, K.M. must be carefully assessed, and the ingestion history reaffirmed.

All solid dosage prescription drugs are required by the US Food and Drug Administration (FDA) to have identification markings. Reference books (e.g., Facts and Comparisons,[86] Physicians' Desk Reference),[87] computerized databases (e.g., IDENTIDEX),[88] and the product manufacturers can assist in identifying solid dosage forms. Websites such as **http://www.pharmer.org**[89] and **http://www.drugs.com**[90] can also be useful in obtaining drug identification information.

The imprint code markings on the green tablet brought to the ED with K.M. and the mother's assistance should be sufficient to correctly identify the medication. Once the tablet has been identified, the maximal number of tablets ingested should be estimated.

In K.M.'s case, the bottle containing the green tablets was unlabeled. In most cases, the label on the medication container can provide information on the identity and number of tablets dispensed. The date the prescription was obtained, the number of estimated doses taken, and the number currently remaining in the medication container can be used to approximate the maximal number of tablets ingested.

K.M's vital signs and symptoms should be monitored closely to evaluate whether her clinical status is consistent with expectations based on the suspected ingestion. Nausea, vomiting, diarrhea, and abdominal pain are common early signs of iron intoxication.[91–96] The absence of symptoms, especially within a short time after the presumed ingestion, should not be interpreted as an indication that a poisoning has not occurred.[91,93–96]

Evaluating Severity of Toxicity

CASE 5-3, QUESTION 4: K.M. weighs 24.2 pounds, appears to be in no distress, and has stopped vomiting. About 25 mL of dark-colored vomitus was recovered, but no tablets are found. The vomitus tested negative for blood. A maximum of seven tablets was ingested based on the mother's recall. What degree of toxicity should be expected in K.M.?

The potential severity of toxicity can be estimated for commonly ingested drugs such as acetaminophen,[97] salicylates,[71] iron,[91] and TCAs[98] because of well-established dose–toxicity relationships. Acute elemental iron ingestions of less than 20 mg/kg are usually nontoxic, doses of 20 to 60 mg/kg result in mild-to-moderate toxicity, and doses greater than 60 mg/kg are potentially fatal.[92,94,96]

The independent verification of the tablet by K.M.'s mother and the tablet imprint indicate that each tablet contained 325 mg of ferrous fumarate in an enteric-coated formulation. Because the dose–toxicity relationship of iron is based on the amount of elemental iron ingested, knowledge of the specific iron salt is important in calculating the ingested dose. Ferrous fumarate contains 33% elemental iron, whereas ferrous gluconate contains 12%, and ferrous sulfate contains 20%.[91,92,94,95] Therefore, each 325-mg ferrous sulfate tablet contains 108 mg of elemental iron. K.M. ingested a maximum of seven enteric-coated ferrous fumarate 325-mg tablets and she weighs 24.2 pounds (11 kg). Her ingestion of approximately 69 mg/kg (108 mg per tablet × 7 tablets = 756 mg total divided by 11-kg patient weight) of iron places her at risk of severe toxicity. Although K.M.'s only symptom is vomiting at this time, absorption could be delayed because she ingested an enteric-coated formulation.

Abdominal Radiographs

CASE 5-3, QUESTION 5: K.M. is expected to experience potentially severe toxicity from her iron ingestion. Why would an abdominal radiograph be useful to verify the number of iron tablets ingested?

In theory, radio-opaque substances (e.g., iron, enteric-coated tablets, chloral hydrate, phenothiazines, heavy metals) can be

visualized in the GI tract by an abdominal radiograph.[99] The ability of a radiograph to detect the presence of a radiodense substance depends on the dosage form, concentration, and molecular weight of the substance. The intact dosage form can often be detected if the tablet has not already disintegrated or dissolved.[99]

Less than one-third of pediatric abdominal radiographs show positive evidence of tablets or granules after iron poisoning.[100] Children are more likely than adults to chew tablets rather than swallow them whole, and false-negative results can occur when whole tablets have not started to disintegrate. If the tablets were chewed, an abdominal radiograph is not likely to be useful for verifying the number of iron tablets ingested. However, an abdominal radiograph after the completion of GI decontamination can help assess whether additional decontamination is needed.[99]

Gastrointestinal Decontamination

CASE 5-3, QUESTION 6: Would gastric lavage or activated charcoal not be indicated for the management of K.M.'s iron ingestion? Why or why not?

When selecting a method of GI decontamination, consider the substance ingested, maximal potential toxicity expected from the drug dosage form, potential time course of toxicity, time elapsed between ingestion and the initiation of treatment, symptoms, and physical examination findings. Decontamination with activated charcoal is not indicated in K.M. because iron tablets are not adsorbed by activated charcoal.[49,91,99] Gastric lavage would also be ineffective because the removal of large undissolved iron tablets from the stomach is limited by the small internal diameter of the gastric lavage tube, especially in pediatric patients.[99,100]

Whole Bowel Irrigation

CASE 5-3, QUESTION 7: What other method of GI decontamination should be considered for K.M.?

Whole bowel irrigation with a polyethylene glycol electrolyte solution can be considered in this case. WBI fluid can be administered orally or by NG tube at a rate of 1.5 to 2 L/hour for adults and at a rate of 500 mL/hour for children.[59,101] Although the ingestion of a large volume of fluid over several hours and the likelihood of nausea and vomiting often result in poor patient compliance, K.M. is hospitalized and the fluid can be infused by NG tube. WBI should be continued until the rectal effluent is clear, which can take many hours.[59,101,102]

MONITORING EFFECTIVENESS OF TREATMENT

CASE 5-3, QUESTION 8: How should the effectiveness of GI decontamination be assessed in the ED?

In order to assess the effectiveness of GI decontamination, the return fluid from the WBI is visually inspected for tablets or tablet fragments. Increasing serum iron concentrations, deteriorating clinical status, or evidence of radiodense tablets in the GI tract on abdominal radiograph are all indications for more aggressive treatment.[92,94,102]

Serum Iron Concentrations

CASE 5-3, QUESTION 9: At this time, K.M. does not appear to be experiencing any CNS or cardiovascular symptoms associated with toxic iron ingestions. She did have one episode of diarrhea that tested negative for blood. A serum iron concentration, obtained about 4 hours after the ingestion, was 480 mcg/dL (normal, 60–160 mcg/dL). What conclusions as to severity or likely clinical outcome can be derived from this serum iron concentration?

The serum iron concentration provides an indication as to whether more aggressive therapy is needed.[96,100,103] The higher than normal serum iron concentration confirms the suspicion that K.M. has ingested iron tablets despite both her current lack of serious symptoms and the absence of tablet evidence in the rectal effluent or by abdominal radiograph.

The time course of absorption is probably the most difficult pharmacokinetic parameter to evaluate with toxic ingestions. Drug concentrations can continue to rise after an overdose despite GI decontamination.[93,95,96,103] This prolongation of absorption time is further complicated when sustained-release or enteric-coated dosage formulations have been ingested because the onset of symptoms is unpredictable.[94]

K.M.'s serum iron concentration of 480 mcg/dL suggests a serious ingestion because peak serum iron concentrations greater than 500 mcg/dL are usually predictive of significant toxicity.[93–96,100,103] This single serum iron concentration does not provide information as to whether the serum concentration is rising or declining or when the serum iron concentration will peak as a result of his iron ingestion.[104] Iron tablets may also clump together and form a bezoar, which can result in prolonged absorption and delay the onset of toxicity.[93,96] Samples for peak serum iron concentration should be obtained 4 to 6 hours after ingestion.[94–96,103] Although K.M.'s serum iron concentration was measured approximately 3 hours after ingestion, another serum iron level is needed in 2 to 4 hours because she ingested an enteric-coated formulation.

Blood Glucose, White Blood Cell Count, and Total Iron Binding Capacity

CASE 5-3, QUESTION 10: K.M. was administered WBI through the NG tube for several hours until the rectal effluent was clear. At this time, K.M. had three more episodes of vomiting and became drowsy and fussy. A repeat serum iron concentration was ordered at 6 hours after ingestion. What other laboratory tests could be helpful in assessing the potential toxicity of iron in K.M.?

Blood glucose concentrations and white blood cell counts usually are increased when serum iron concentrations are greater than 300 mcg/dL. A white blood cell count greater than 15,000/µL and a blood glucose concentration greater than 150 mg/dL within 6 hours of ingestion generally suggest a higher likelihood of severe toxicity.[93] These tests provide supplemental confirmation of iron intoxication and may be useful in medical facilities in which serum iron concentrations cannot be obtained. These laboratory tests are not routinely monitored in iron poisoning because of the poor sensitivity (about 50%).[94] Treatment should not be based on a white blood cell and glucose concentration alone.[93–95,100] If a patient with severe iron toxicity presents to a health care facility that cannot perform timely serum iron levels, either the blood iron sample must be sent to a laboratory that can do the testing quickly or the patient must be transferred to a health care facility that can do serum iron testing for patient monitoring.

It was once believed that if the serum iron concentration exceeded the total iron binding capacity concentration, it would indicate substantial iron toxicity. However, this theory has not held up, and the total iron binding capacity test is no longer used to monitor iron toxicity.[99]

Stages of Iron Toxicity

CASE 5-3, QUESTION 11: It is now 6 hours since K.M. ingested the iron tablets. Her second serum iron concentration is not yet available. She continues to be drowsy and fussy, and she has missed her usual nap. She is still vomiting. Why is K.M.’s relatively mild course at this time not particularly reassuring?

The time between the ingestion of an overdose of drugs and the development of severe toxicity can be delayed. It is unclear why there may be an asymptomatic period, but it may be secondary to delayed absorption of the ingested drug, the time required for the drug distribution, or the time needed to form a toxic metabolite. Consequently, K.M. may still exhibit further symptoms of severe toxicity. Four distinct stages of symptoms can be encountered with iron toxicity.[91–96]

STAGE I

Stage I symptoms usually take place within 6 hours of ingestion, during which nausea, vomiting, diarrhea, and abdominal pain occur, probably secondary to the erosive effects of iron on the GI mucosa. The caustic effects of free iron can cause bleeding as evidenced by blood in the vomitus and stool. In more severe intoxications, CNS and cardiovascular toxicity can be present during stage I.[93–96]

STAGE II

The second stage of iron toxicity has been suggested as a period of reduced symptoms and an apparent clinical improvement. This stage can last for up to 12 to 24 hours after the ingestion and could be misinterpreted as resolving toxicity. This stage may represent the time needed for the absorbed iron to distribute throughout the body before systemic symptoms develop.[91] In most severe cases, stage II does not occur and the patient's condition continues to deteriorate.[93–96]

STAGE III

Stage III generally occurs 12 to 48 hours after iron ingestion and is characterized by CNS toxicity (e.g., lethargy, coma, seizures) and cardiovascular toxicity (e.g., hypotension, shock, pulmonary edema). Metabolic acidosis, hypoglycemia, hepatic necrosis, renal damage, and coagulopathy can also happen during this stage.[93–96]

STAGE IV

The final stage is apparent 4 to 6 weeks after acute iron ingestion and consists of delayed-onset GI tract sequelae secondary to the initial local toxicity. In this stage, prior tissue damage can progress to gastric scarring and strictures at the pylorus, resulting in permanent abnormalities of GI function.[93–96]

Patients can present to the health care facility in any stage of iron toxicity and can have a fatal outcome in any stage. Determination of a stage of toxicity should be based on clinical symptoms rather than time of ingestion.[95]

Deferoxamine Chelation

CASE 5-3, QUESTION 12: The second serum iron concentration that was obtained 6 hours after ingestion has increased from 480 to 560 mcg/dL. The child has continued to vomit and appears pale. What criteria are most important in determining whether K.M. is a candidate for the antidote deferoxamine?

Deferoxamine (Desferal) chelates iron by binding ferric ions in plasma to form the iron complex ferrioxamine.[94] Deferoxamine prevents iron toxicity at a cellular level by removing iron from mitochondria.[92] Unfortunately, deferoxamine is not a very effective antidote because a relatively small amount of iron is bound (approximately 9 mg of iron to 100 mg of deferoxamine).[104,105] The iron–deferoxamine complex is primarily excreted renally as ferrioxamine.[92,94,95] Renal elimination of the ferrioxamine usually results in a pinkish-orange urine, often described as “vin rose.”[92,94,95] Deferoxamine therapy should be initiated when serum iron concentrations exceed 500 mcg/dL and when symptoms of iron toxicity (e.g., GI symptoms, hemorrhage, coma, shock, seizures) are present.[92–95] K.M. is experiencing symptoms, she presumably ingested up to 69 mg/kg of elemental iron, and iron absorption appears to be ongoing based on the increase in her serum iron concentration. Therefore, K.M. should be treated with deferoxamine.

DEFEROXAMINE DOSE

CASE 5-3, QUESTION 13: What dose of deferoxamine should be prescribed for K.M., and how should it be administered?

Deferoxamine is most effective when administered intravenously as a continuous infusion because of its short half-life (76 ± 10 minutes).[95,104] Clinically, a slow IV infusion is preferred over intramuscular administration because the IV dose is better controlled, less painful, and better absorbed than an IM dose.[95,96] Deferoxamine is usually administered in a continuous IV infusion at a dose of 15 mg/kg/hour. However, doses up to 45 mg/kg/hour have been used in patients with severe iron poisoning.[93–96,104] Administering IV boluses of deferoxamine too rapidly can result in hypotension.[94,96,104,105] According to the manufacturer, the total deferoxamine dose should not exceed 6 g every 24 hours in children or adults, but adverse effects have not been seen in patients who received more than 6 g every 24 hours.[105]

Deferoxamine therapy should be initiated in K.M. at a lower rate of about 8 mg/kg/hour, and her clinical status should be monitored closely. If the dose is tolerated, the rate can be increased every 5 minutes until the desired rate of 15 mg/kg/hour is reached.[90]

MONITORING AND DISCONTINUATION

CASE 5-3, QUESTION 14: K.M. is admitted to the pediatric ICU shortly after the initiation of a deferoxamine infusion at 8 mg/kg/hour. How should deferoxamine therapy be monitored, and when should it be discontinued?

The rate of deferoxamine infusion should be increased with symptoms of severe iron toxicity, and decreased if patients experience adverse effects.[93,94,96,105] Treatment should continue until the serum iron concentration is less than 100 mcg/dL and symptoms of iron toxicity resolve.[105] Patients usually require chelation therapy for about 1 to 2 days, depending on the severity of symptoms.[93–95] Unnecessarily prolonged chelation therapy should be avoided because deferoxamine infusion for more than 24 hours has been associated with the development of acute respiratory distress syndrome.[93–98]

The urine color change to vin rose indicates ferrioxamine in the urine.[92,96] The lack of a color change is not a reliable indication of adequate deferoxamine therapy because not all patients experience vin rose urine.[92,96] There is also no correlation between amount of iron ingested, serum iron concentration, and the urine color change.[92]

Deferoxamine can interfere with some laboratory methods used to measure serum iron concentrations and cause falsely low values.[92,93,103,106] Atomic absorptive spectroscopy is a recommended method for monitoring serum iron concentrations once deferoxamine treatment has been started.[105] When initiating

---

deferoxamine therapy, the clinical laboratory should be contacted to clarify whether deferoxamine will interfere with their serum iron analysis.

Outcome of Patient K.M.

K.M. was admitted to the pediatric ICU overnight and treated with a constant infusion of deferoxamine at 15 mg/kg/hour for 13 hours. Her GI symptoms resolved, she became more alert, and her vital signs were stable. Her serum iron level was 70 mcg/dL the next morning, and she was discharged home that afternoon.

ASSESSMENT OF CENTRAL NERVOUS SYSTEM DEPRESSANT VERSUS ANTIDEPRESSANT INGESTION

Validation of Ingestion

CASE 5-4

QUESTION 1: A.G., a 40-year-old man, was found unconscious in a pool of vomitus with a suicide note. The note stated that he had ingested 30 of his pills. A.G.'s 75-year-old mother called paramedics. When the paramedics arrived, A.G.'s heart rate was 150 beats/minute, BP was 115/70 mm Hg, and respirations were 14 breaths/minute and shallow. A.G. responded only to painful stimuli. The paramedics immediately started an IV line after completing their assessment of his ABCs. Why should the drug overdose information from this suicidal patient be validated?

Assessing the accuracy of historical information in adult drug exposures is difficult, and many health care professionals question the validity of information, especially from suicidal patients.[22–25,27] The ingestion history could be inaccurate because the patient's altered mental status might prevent accurate recollection of what occurred. He may also try to intentionally mislead health care providers to avoid appropriate care. Studies have demonstrated poor correlation between reported drug ingestions and urine drug test results.[23–25,27,32,33,107] There are also numerous false-positive results that can be misleading because of drug interference.[108,109]

Urine drug screens generally detect all recent drug and substance use, rather than just an overdosed drug. Urine drug screen results, therefore, are not reliable indicators of acute exposures. Every effort should be made to validate the history with information from other sources. In suicidal patients, one should consider all drugs that may have been available to the patient, as well as the patient's presenting symptoms, laboratory tests, and information obtained from family members, police, paramedics, and other individuals who know the patient.[22–25,27]

Interventions by Protocol

CASE 5-4, QUESTION 2: In addition to managing the ABCs, what pharmacologic interventions should be authorized for the paramedics to administer to A.G. in addition to the initiation of an IV solution?

GLUCOSE AND THIAMINE

Emergency medical service personnel often have protocols directing them to treat patients who are unconscious from an unknown cause. These protocols generally include administration of glucose, thiamine, and naloxone.[23,27,60,110] If paramedics cannot measure a blood glucose concentration immediately, A.G. should be given 50 mL of 50% dextrose to treat possible hypoglycemia. The risks of hyperglycemia from this dose of glucose are negligible relative to the significant benefits if the patient is hypoglycemic. Thiamine should be administered concurrently with glucose because glucose can precipitate Wernicke–Korsakoff complex in thiamine-deficient patients[111] (see Chapter 90, Substance Abuse Disorders). Wernicke encephalopathy is a reversible neurologic disturbance consisting of generalized confusion, ataxia, and ophthalmoplegia. Korsakoff psychosis is believed to be irreversible and is associated with a more prolonged deficiency of thiamine.[111,112] The unconscious patient should also be evaluated for blood loss, sepsis, hypoxia, and evidence of head trauma.[25]

NALOXONE

The pure opioid antagonist, naloxone, is indicated for the treatment of respiratory depression induced by opioids,[110,113] but many emergency medical service protocols authorize paramedics to routinely administer naloxone to all patients with any decreased mental status.[114] Naloxone reportedly has reversed coma and acute respiratory depression in intoxicated patients who have no evidence of opioid use.[60,112] The response of these patients to naloxone might have been secondary to opioids that were not detected by the urine toxicology screens (e.g., oxycodone, methadone, fentanyl). Reports of naloxone success in patients without opioid use could also have been the result of responses to other stimuli rather than a response to naloxone.

Administering naloxone to an opioid-addicted patient can precipitate withdrawal symptoms (e.g., agitation, combativeness, vomiting, diarrhea, lacrimation, rhinorrhea) that can further complicate the intoxication picture.[60] Small doses of naloxone should be administered initially to determine the patient's response to this medication. Violent and aggressive behavior can result when sudden increased consciousness is induced by naloxone.[27] This can complicate emergency care in an emergency transport vehicle and put caregivers and patients at risk for trauma.[60]

Initial Treatment

CASE 5-4, QUESTION 3: The paramedics arrive at the ED with A.G. 30 minutes after his mother called. A.G.'s heart rate in the ED is 155 beats/minute, BP is 89/50 mm Hg, and respirations have decreased from 14 to 9 breaths/minute, with assisted ventilation. A.G. remains unresponsive. The paramedics were unable to find any prescriptions or other medications in the house. The mother thinks her son was taking medication for depression. The medical team will try to obtain more details from A.G.'s pharmacy. What initial treatment should be provided for A.G. in the ED?

A.G. should be intubated and mechanically ventilated with 100% oxygen because of his shallow, slow respirations and the likelihood that vomitus could have been aspirated into his lungs. A bolus of IV fluid should be administered to A.G. to determine whether an increase in intravascular fluid volume will increase his BP and improve his mental status.[22,40]

Antidotes

CASE 5-4, QUESTION 4: A.G. fills his prescriptions at several pharmacies and it is taking a while to obtain his medication list. What antidotes can be administered in the ED for diagnostic purposes? Should flumazenil (Romazicon) be administered?

Theoretically, antidotes such as naloxone, flumazenil, deferoxamine, and digoxin-specific antibody-FAB fragments could be administered in a hospitalized setting to identify an unknown toxin.[22,26,27,113,115,116] However, the cost and time required for administration, and increased risks from these antidotes, preclude their use for diagnostic purposes without some plausible suspicion of a specific drug ingestion.[113,115]

Organ System Evaluations

CASE 5-4, QUESTION 5: How can the initial physical assessment, using an organ systems approach, help in identifying the drugs ingested by A.G.?

The patient's ABCs and CNS and cardiopulmonary functions should be assessed with special attention to clinical manifestations that suggest ingestion of a specific class of drugs.[27,40] A.G.'s history of depression suggests that antidepressants, antipsychotics, lithium, or benzodiazepines are candidates for ingestion. An organ system evaluation will help determine whether these (or other) drugs might have been ingested. Commonly used nonprescription medications such as aspirin, acetaminophen, decongestants, and antihistamines, should also be considered because adult drug ingestions usually involve more than one drug.

CENTRAL NERVOUS SYSTEM FUNCTION

Changes in CNS function are probably the single most common finding associated with drug intoxication.[27] CNS depression or stimulation, seizures, delirium, hallucinations, coma, or any combination of these can be seen in intoxicated patients. CNS changes can be the direct result of an ingested drug or may be attributed to other underlying CNS processes or medical conditions.[116] Clinical manifestations of drug overdoses may differ depending on where the patient is in the time course of the intoxication, and the amount of drug(s) ingested.[27,64]

Drugs with anticholinergic properties can produce disorientation, confusion, delirium, and visual hallucinations early in the course of the intoxication; coma can become apparent as toxicity progresses. Generally, overdoses with anticholinergic drugs do not produce true hallucinations, but rather pseudohallucinations. When a patient with an intact baseline mental status presents with psychosis, paranoia, or visual hallucinations, CNS stimulants such as cocaine or amphetamines should be considered.[30,65]

Drug intoxication–induced alterations in CNS function are initially difficult to distinguish from those caused by underlying psychiatric disorders, trauma, hypoxia, or metabolic disorders, such as hepatic encephalopathy or hypoglycemia. However, as time passes, decreased CNS function secondary to drug toxicity is more likely to wax and wane in severity in contrast to the persistent CNS depression that occurs with significant trauma or metabolic disorders. Drug toxicity also rarely produces focal neurologic findings. Changes in pupil size, reflexes, and vital signs can provide insights into the pharmacologic class of drug involved in the intoxication.[23,27,28]

CNS depression, seizures, disorientation, and other CNS changes that are commonly associated with psychiatric drugs should be evaluated carefully in A.G. For example, A.G.'s pupil size would most likely be dilated if he had ingested a TCA because of the anticholinergic effects of these drugs. TCA intoxications can also cause myoclonic spasms,[27] which are often difficult to differentiate from seizure activity caused by TCA overdoses, although the spasms are often asymmetric and more persistent.[117]

CARDIOVASCULAR FUNCTION

Assessment of heart rate, rhythm, conduction, and measurements of hemodynamic function can also be used to help identify the type of drug ingested. Overdoses of sympathomimetic drugs usually increase heart rate, while overdoses of cardiac glycosides or β-blockers can slow the heart rate. Although drugs can increase or decrease heart rate directly, indirect cardiac effects (e.g., reflex tachycardia in response to hypotension) also need to be considered. Abnormal heart rates produced by drug overdoses are usually not treated unless accompanied by hypotension or severe dysrhythmias.[27,40]

PULMONARY FUNCTION

Evaluating the rate and depth of respiration and the effectiveness of gas exchange in an intoxicated patient can also help identify drugs ingested. A decrease in respiratory rate is commonly associated with the ingestion of CNS depressants. An increased respiratory rate and depth is generally associated with CNS stimulant toxicity and can also be secondary to respiratory compensation for a drug-induced metabolic acidosis.[27] Aspiration of gastric contents after vomiting is common in drug ingestions. Aspiration pneumonitis is the most common pulmonary abnormality associated with significant intoxications.[43] Noncardiogenic acute pulmonary edema has been associated with salicylate overdoses[80] (especially with chronic intoxications) and drugs of abuse (e.g., cocaine and heroin).[114,118–124]

TEMPERATURE REGULATION

Body temperature is an important and sometimes overlooked parameter when assessing potential intoxications.[27,40] Decreased mental status is often associated with a loss of thermoregulation, resulting in a body temperature that falls or increases toward the ambient temperature. Increased body temperature (hyperthermia) caused by overdoses of CNS stimulants (e.g., cocaine, amphetamines, ecstasy), salicylates, hallucinogens (e.g., phencyclidine), or anticholinergic drugs or plants (e.g., jimsonweed) can have serious consequences.[27,29,40] Body temperature should be measured rectally to obtain an accurate representation of core body temperature.[125]

Hyperthermia caused by drug overdoses is commonly seen in hot, humid environments or when the intoxication is associated with physical exertion, increased muscle tone, or seizures. In these patients, it is important to obtain renal function tests (e.g., BUN, serum creatinine) and a serum creatine kinase measurement to determine whether rhabdomyolysis has occurred secondary to breakdown of muscle tissue.[27,40,125]

GASTROINTESTINAL FUNCTION

The GI tract should be assessed for decreased motility because drug absorption can be delayed or prolonged.[27,126,127] When this is the case, decontamination may be beneficial after an oral ingestion even if a long time has elapsed since the ingestion. The presence of blood in either emesis or stool may suggest ingestion of a GI irritant or caustic substance.[128]

SKIN AND EXTREMITIES

The physical examination should include a thorough examination of the body surface for causes of trauma that may also explain the patient's condition. Examination of the skin and extremities can provide evidence of drug intoxication, especially with IV or subcutaneous drug injection needle marks.[27] Drugs can be hidden in the rectum or vagina.[27] Drug patches (e.g., fentanyl) may be found in hidden areas of the body such as the back of the neck or scrotum. Fluid-filled bullae at gravity-dependent sites that have been in contact with hard surfaces for a long time suggest prolonged coma.[27] Muscle tone should also be assessed.[30] Increased tone or myoclonic spasms can be caused by some drug overdoses (e.g., TCAs) and can produce rhabdomyolysis or hyperthermia.[27,125] Dry, hot, red skin may also be an indication of anticholinergic toxicity.[27,40]

In summary, an organ system assessment of A.G. can provide useful insights into the identity of drugs that might have been ingested, the viability of organ function that might have been adversely affected, and the treatment needed.

Laboratory Tests

CASE 5-4, QUESTION 6: What laboratory tests should be ordered for A.G.?

The laboratory assessment of an intoxicated patient should be guided by the history of the events surrounding the ingestion, clinical presentation, and past medical history.[22,129] The status of oxygenation, acid–base balance, and blood glucose concentration must be determined, especially in patients with altered mental status such as A.G.[40] Oxygenation can be assessed initially by pulse oximetry and acid–base status by ABGs and serum electrolyte concentrations.[129,130] A.G. was given oxygen and a bolus of IV fluid on arrival at the ED, and paramedics administered glucose during transportation.

A medical history of organ dysfunction or medical disorders (e.g., diabetes, hypertension) that can damage organs of elimination (e.g., kidney, liver) will also guide the need for laboratory tests. A serum creatinine concentration and liver function tests (e.g., aspartate aminotransferase [AST], alanine aminotransferase [ALT]) should be ordered. Other more specific tests reflective of his past medical history can be ordered subsequent to dialogue with his psychiatrist. A complete blood cell count, complete chemistry panel, serum osmolality, and other baseline laboratory tests should be obtained.[27] Pregnancy tests should be considered in female patients of childbearing age because unwanted pregnancies are common causes of overdose.[131,132]

A baseline electrocardiogram (ECG) should be obtained when exposure to a cardiotoxic drug is suspected or whenever the cardiovascular or hemodynamic status is altered.[23,26,40,130] A 12-lead ECG should be ordered because A.G. is likely to have ingested a psychotropic agent. Continuous cardiac monitoring should be instituted because of the significant cardiotoxicity associated with overdoses of these agents. Patients with severe TCA overdoses frequently present with symptoms of coma, tachycardia with a widened QRS interval, seizures, hypotension, and respiratory depression.[133–136]

A chest radiograph is useful when the potential exists for either direct pulmonary toxicity or aspiration.[23,26] A chest radiograph is indicated because A.G. had vomitus in his mouth and TCAs are associated with the development of acute respiratory distress syndrome and pulmonary edema.[133,137,138]

Qualitative Screening

CASE 5-4, QUESTION 7: Should A.G.'s urine and blood be screened to assist in identifying the ingested substance? Explain your rationale.

Toxicology laboratory testing can be used to identify the substances involved in a toxic exposure, to exclude substances, or to measure the concentration of substances in serum or other biological fluids.[24,129,130] The identification and quantification of compounds should be considered as two distinct types of toxicologic testing.[24,139] Qualitative screening is used to identify which substance or class of substances is involved in the toxic exposure. Quantitative testing determines how much of a known substance is present.[24]

Screening of various biological fluids can identify unknown substances. Urine is screened much more commonly than blood, whereas gastric fluid is rarely evaluated. A urine drug screen is preferred to a blood drug screen because urine generally contains a higher concentration of a drug and its metabolites than other body fluids.[140]

When reviewing the results of urine screening panels for drugs and other substances, one must remember that the presence of a substance in urine is not necessarily related to a concurrent toxicity. A positive result on a urine screening panel merely indicates that the patient has ingested or has been exposed to the substance, but it does not differentiate between toxic and nontoxic doses. If a drug and its metabolites are eliminated slowly into the urine for a prolonged time, and if the testing methodology detects small concentrations of the substance, urine drug screening could identify the presence of a substance days, weeks, or even months after the exposure (e.g., marijuana).[24,130]

It is important to know which drugs or substances are tested at a given laboratory. Many laboratories restrict the number of drugs for which they test because 15 drugs account for more than 90% of all drug overdoses.[32] Some urine toxicology screens only detect common drugs of abuse (e.g., amphetamines, barbiturates, benzodiazepines, cocaine, marijuana, opioids).[130] Some drugs of abuse are not detected on routine drug screening (e.g., gamma hydroxybutyrate, ketamine, flunitrazepam).[24] Some analyses detect only antibodies to drug metabolites. For example, a benzodiazepine screen detects oxazepam, a common benzodiazepine metabolite. However, alprazolam and lorazepam are not metabolized to oxazepam and will not be detected in a urine screen. Likewise, an opioid screen may not detect the synthetic opioids such as fentanyl and methadone.[130]

Results of qualitative toxicology screening tests are difficult to interpret. False negatives, false positives, cross-reactivity with related drugs, chronicity of exposure, and length of time since last exposure all complicate results.[108,109,130] Urine toxicology screen results rarely change clinical management of the patient. Monitoring mental, cardiovascular, and respiratory status and other laboratory parameters provide better clues than the results of a urine toxicology screen.[23,24,129,130,139]

Toxicology screening can be appropriate when the history of a suspected toxic exposure is unavailable, inaccurate, or inconsistent with the clinical findings.[24] However, it is important to know which drugs are detected on a given toxicology screen.[130] A comprehensive qualitative urine drug screen can be considered for A.G. because information about the substance(s) he ingested is not yet known.

Quantitative Testing

CASE 5-4, QUESTION 8: Should a quantitative toxicology laboratory test be ordered for A.G. as well? Explain your rationale.

After a qualitative urine analysis for drugs, a quantitative analysis of drug concentration in blood can help determine the severity of toxicity and the need for aggressive interventions (e.g., hemodialysis).[24,33,130,139] Quantitative tests are especially useful when assessing the potential toxicity of drugs with delayed clinical toxicity or when the toxicity primarily is caused by metabolites (e.g., ethylene glycol, methanol). The concentration of a drug in serum is sometimes much more predictive of end-organ damage than clinical findings (e.g., acetaminophen effect on the liver).

Quantifying the amount of drug in serum is useful when (a) the concentration of the substance correlates with toxic effects, (b) the turnaround time for results is rapid, and (c) treatment can be guided by the serum concentration.[32,132,142] To aid in the care of poisoned patients, stat quantitative serum concentrations of acetaminophen, carbamazepine, carboxyhemoglobin, digoxin, ethanol, ethylene glycol, iron, lithium, methanol, methemoglobin, phenobarbital, salicylates, and theophylline should be available at laboratories of large health care facilities.[23,24,33,129,139]

When blood samples are collected to quantitate potentially intoxicating substances, as much information as possible should be obtained about the time course of events to determine whether absorption and distribution of the substance is complete. Serial samples may be needed to determine whether significant

---

absorption is still occurring.[29,30] In contrast to the interpretation of therapeutic serum concentrations of chronically administered drugs, the serum concentration of a substance ingested in an overdose is not likely to be at steady state.

Quantitative toxicologic testing will likely not benefit A.G. at this point in time because the identity of the ingested substance is unknown. Nevertheless, a serum ethanol concentration could be obtained because alcohol is often ingested concurrently in overdose situations.[132] Most poison centers also recommend obtaining a quantitative acetaminophen level on all intentional ingestions because serious hepatotoxicity can occur if acetaminophen ingestion is missed.[24,129,130]

Assessment

CASE 5-4, QUESTION 9: A.G.'s clinical status has not changed in the past 10 minutes. A urine toxicology screen, blood acetaminophen, blood alcohol, and ABGs have been ordered. The 12-lead ECG shows a prolonged QRS interval of 0.13 seconds (normal, <0.1 seconds). No antidotes have been administered. A.G.'s physical examination did not detect any evidence of trauma to his head. His pupils were dilated and slowly responsive to light, and his bowel sounds were hypoactive. What conclusions can be made at this time with regard to the likely substance ingested by A.G?

Although the ingested substance still has not been specifically identified, the available data provide some clues as to the likely pharmacologic class of drug that was ingested. The presence of CNS depression (A.G. is unresponsive), slowed ventricular conduction (widened QRS on ECG), tachycardia (heart rate, 155 beats/minute), hypotension (BP, 89/50 mm Hg), and decreased GI motility (hypoactive bowel sounds), and the history of a possible depressive illness (history from mother) are all consistent with a TCA drug overdose. The antidepressant could have been ingested alone or with other agents.

Antidepressant Toxicities

CASE 5-4, QUESTION 10: How would the different toxicities of the many available antidepressants affect the treatment of A.G.?

The major pharmacologic effects and toxicities of the antidepressants are similar for all drugs within the same class. When a specific drug within a therapeutic class has not yet been identified, the overdose should be managed as if the ingested drug can produce the most severe toxicity of any drug in the class. Therefore, A.G.'s presumed antidepressant drug overdose should be evaluated and managed initially as TCA (e.g., amitriptyline) ingestion.[135,141] Antidepressants with different structures and actions (e.g., trazodone [Desyrel], fluoxetine [Prozac], sertraline [Zoloft]) generally do not produce toxicity as severe as that of the TCAs.[135,141,142]

Gastrointestinal Decontamination

CASE 5-4, QUESTION 11: If a TCA ingestion is presumed, why might GI decontamination be appropriate at this time?

The longer GI decontamination is delayed relative to the time of ingestion, the less effective it is likely to be because drug absorption will already have occurred. Because the time of ingestion is unknown and A.G. is unresponsive, he probably already has absorbed significant amounts of the drug, making him more vulnerable to aspiration. Additionally, A.G. might already have aspirated because he was found in a pool of vomitus. TCA overdoses can also cause seizures, which would be a relative contraindication to GI decontamination. In consideration of these concerns, many would not support GI decontamination for A.G.[41–44,51–54]

Others might support GI decontamination because TCAs have strong central and peripheral anticholinergic properties that slow GI emptying, which could result in erratic absorption and delayed toxicity, but A.G. would first need to be intubated to protect his airway. Furthermore, TCAs have a large volume of distribution (10–50 L/kg), and both the parent drug and its metabolite undergo enterohepatic recirculation. The half-life of TCAs in overdose situations is 37 to 60 hours. For those reasons, activated charcoal could be reasonably administered in an effort to adsorb any drug that may not yet be absorbed from the GI tract.[49]

Repeated doses of activated charcoal have been used to increase the elimination of TCAs because of the long half-life of TCAs and the enterohepatic recirculation. In clinical studies, multiple-dose activated charcoal has increased the elimination of amitriptyline, but the data are insufficient to support or exclude its use.[47]

MONITORING EFFICACY

CASE 5-4, QUESTION 12: How should the effectiveness of GI decontamination be monitored in A.G.?

If activated charcoal is administered, A.G. must first be intubated to protect his airway, and the charcoal must be administered via NG tube because he is unconscious. The insertion of the NG tube could stimulate the gag reflex, causing vomiting and possible aspiration. A.G.'s lung sounds should be monitored closely to determine whether aspiration pneumonitis is developing, particularly because AG. was found unconscious and had already vomited.

Activated charcoal, especially in multiple doses, can produce ileus, GI obstruction, or intestinal perforation, particularly when administered to patients who have ingested drugs that slow GI motility.[47,49,101] Bowel sounds must be monitored frequently to ensure that an ileus is not developing. Once the patient passes a charcoal-laden stool, the activated charcoal can be considered to have successfully passed through the GI tract.

Sodium Bicarbonate and Hyperventilation

CASE 5-4, QUESTION 13: According to A.G.'s psychiatrist, he prescribed amitriptyline 100 mg at bedtime for his severe depression. How does this new information alter A.G.'s treatment plan?

This information confirms the assumptions that a TCA was ingested. It also specifically identifies the drug ingested. In TCA ingestions, severe toxicity has been associated with doses of 15 to 25 mg/kg.[98] A.G. ingested a total of 3,000 mg based on his suicide note that said he took 30 tablets. If he weighs about 70 kg and was truthful about the amount taken, he ingested a significantly toxic dose (about 43 mg/kg).

On the ECG, TCA toxicity will manifest as tachycardia with prolongation of the PR, QTc, and QRS intervals, ST and T-wave changes, and abnormalities of the terminal 40-millisecond vector.[98,117,133,136,142–146] TCAs have anticholinergic, adrenergic, and quinidine-like membrane effects on the heart.[117,133,135,141,144] It is believed that the anticholinergic effect causes the tachycardia and the quinidine-like effect causes the ECG changes.

In addition, TCAs are sodium-channel blockers.[147] Sodium-channel blockade slows the maximum uptake stroke of phase 0 of the action potential and decreases automaticity. Blockade decreases conduction velocity in the Purkinje fibers, which increases the QRS interval.[144] Myocardial depression, ventricular tachycardia,

and ventricular fibrillation are the most common causes of death from TCAs.[136]

Therefore, admission to the ICU with continuous cardiac monitoring is essential for A.G.[143]

The primary therapy for reversing ventricular arrhythmias and conduction delays is alkalinization of the serum and sodium loading with IV hypertonic sodium bicarbonate.[117,133,135,136,144,145,148] Indications for sodium bicarbonate include hypotension, widened QRS interval (more than 100 milliseconds), right bundle branch block, and wide complex tachycardia.[135,145] Alkalinization increases serum protein binding of the TCAs and reduces the amount of free active drug (likely a minor consideration).[116,133,136,145] Correction of the serum pH is beneficial because underlying acidosis worsens TCA-induced cardiotoxicity.[145] Furthermore, sodium bicarbonate has been found useful even in patients with a normal pH because sodium bicarbonate purportedly overcomes the sodium-channel blockade and reduces cardiotoxicity.[145,147]

On the basis of A.G.'s tachycardia and a widened QRS segment on ECG, he should be treated with IV sodium bicarbonate with the goal of achieving an arterial pH of 7.5 to 7.55.[136,145] Sodium bicarbonate could have been administered earlier because the suspicion of an antidepressant overdose was strong initially, his ECG demonstrated QRS widening and worsening myocardial conduction, and his BP continued to decline from the time he was first seen by the paramedics. If not monitored closely, the use of IV sodium bicarbonate could introduce the risk of sodium overload and subsequent pulmonary edema.[98,146]

An alternative is to hyperventilate the patient to a pH of 7.5 by adjusting his ventilator setting, thereby reducing the cardiotoxicity of the TCA.[133,136,146] The combination of IV bicarbonate and mechanical ventilation is more likely to produce severe alkalemia. Careful and frequent monitoring of the serum pH of patients on dual therapy is essential.[133,147]

MONITORING EFFICACY

CASE 5-4, QUESTION 14: How should the sodium bicarbonate therapy in A.G. be monitored?

Patients intoxicated with TCAs often present with severe acidosis. Large doses of sodium bicarbonate may be required to normalize the arterial pH. The efficacy of sodium bicarbonate administration can be evaluated by monitoring acid–base status using ABGs, especially if the patient is also being ventilated mechanically.[133,147,148]

Sodium bicarbonate should be administered IV as a bolus of 1 to 2 mEq/kg for a 1- to 2-minute period. Continuous ECG monitoring is needed to monitor results of the bolus on cardiac abnormalities. Repeat bolus doses are administered as needed until the QRS interval narrows and tachycardia slows. Blood pH should be tested after several boluses to determine whether a target pH of 7.5 to 7.55 has been obtained.[145] At a minimum, ABGs should be determined within an hour of starting sodium bicarbonate therapy to determine pH response.[148] Bicarbonate boluses can be followed by a constant sodium bicarbonate infusion of 150 mEq/L to maintain an alkaline pH.[145] ABGs must be monitored frequently to ensure a response.[133,147,148] Serial ECGs to measure the QRS interval are useful for evaluating the efficacy of sodium bicarbonate therapy. A widened QRS interval will generally normalize after the systemic pH has been increased to about 7.5.[148]

Seizures

CASE 5-4, QUESTION 15: A.G. gradually developed more severely altered mental status and became comatose, not responding even to painful stimuli. He suddenly experienced a tonic–clonic seizure, which lasted about 1 minute and terminated spontaneously. Should anticonvulsant therapy be initiated for A.G. at this time?

CNS toxicity is common in TCA overdoses. Symptoms include agitation, hallucinations, coma, myoclonus, and seizures.[117,133–136] Seizures can cause significant increases in acidosis and increase cardiotoxicity. Seizures are often seen immediately before cardiopulmonary arrest. Because of the severe consequences of prolonged seizures, aggressive drug treatment with rapid onset of action is indicated, and benzodiazepines are the drugs of choice.[133,136]

Drug overdose–induced grand mal seizures are most commonly single seizures that terminate before drug therapy can be administered.[135] Seizure activity is not expected to persist, so instituting long-term anticonvulsant therapy is not indicated. However, if A.G.'s seizure did not stop within 1 to 2 minutes, a benzodiazepine would have been indicated.[117,133,136] The onset of action of phenobarbital is too slow for acute seizures, and phenytoin is usually ineffective in treating drug toxicity–related seizures.[117] After a seizure, the patient may become more acidotic and hypotensive.[136] Blood gases, creatine kinase, and ECG changes should be monitored immediately after a seizure.

Interpretation of Urine Screens

CASE 5-4, QUESTION 16: A.G.'s BP fell to 80/42 mm Hg, and dopamine was started. His pH on repeat ABGs was 7.20. A.G.'s ECG normalized after the administration of 150 mL of sodium bicarbonate by IV bolus. After dopamine, his BP increased to 100/56 mm Hg, and seizure activity ceased. The urine drug screen results were positive for amitriptyline and nortriptyline. Acetaminophen, salicylates, and ethanol were not detected in his blood. Does the presence of nortriptyline indicate that A.G. has ingested other drugs in addition to his amitriptyline?

Nortriptyline is a metabolite of amitriptyline and, therefore, was identified on the urine drug screen. Metabolites, as well as the parent compound, are often identified on comprehensive urine drug screens.[132]

Duration of Hospitalization

CASE 5-4, QUESTION 17: How long should A.G. be monitored?

A.G. should be admitted to the ICU and monitored until all evidence of CNS and cardiovascular toxicity has been reversed.[117] There is some controversy over how long symptomatic patients should be observed. Some believe symptomatic patients need cardiac monitoring for 24 hours after ingestion.[135] Others believe TCA overdose patients need to be monitored until they are symptom-free for 24 hours because of a few reports of late development of symptoms.[139] However, 98% of signs of cardiotoxicity and arrhythmias are seen within the first 24 hours after TCA ingestion.[117,134] Because the incidence of late-occurring symptoms is rare, most patients are discharged after they are fully awake.[133] After the toxicity has completely resolved, A.G. should be evaluated by a psychiatrist to determine whether he should be admitted for inpatient treatment of his suicidal ideation.[133–135]

Outcome of Patient A.G.

A.G. had no further seizure activity. He remained on a dopamine infusion for 8 hours and required several more boluses of IV sodium bicarbonate. The next afternoon, he started to awaken and expressed regret that his suicide attempt was not successful. Arrangements were made to transfer him to an inpatient psychiatric hospital once he was medically cleared.

ASSESSMENT OF ACETAMINOPHEN INGESTION

Mechanism of Hepatotoxicity

CASE 5-5

QUESTION 1: B.W., a 18-year-old woman who is about 30 weeks pregnant, presents to the ED 8 hours after ingesting 40 acetaminophen 500-mg tablets. She is depressed and hoped to end her pregnancy by ingesting acetaminophen. Her pregnancy was unplanned, and she has received no prenatal care. B.W. has vomited spontaneously 6 times since the ingestion and is complaining of abdominal pain; her heart rate is 95 beats/minute, BP is 110/74 mm Hg, and temperature is 98.5°F. B.W. does not have any chronic diseases, and the remainder of her medical history is unremarkable. How does an overdose of acetaminophen cause toxicity?

Acetaminophen is metabolized in the liver by glucuronidation and sulfation. The mixed-function oxidase system cytochrome P-450 (CYP) 2E1 metabolizes a portion of the acetaminophen to the highly reactive metabolite N-acetyl-p-benzoquinoneimine (NAPQI). In therapeutic doses, this metabolite is detoxified in the liver by glutathione. At toxic serum acetaminophen concentrations, the glucuronidation and sulfation metabolic pathways become saturated. Usually, NAPQI is detoxified by conjugation with glutathione, but increased amounts of the toxic metabolite deplete hepatic glutathione stores. When glutathione stores are decreased to about 30% of normal, the toxic metabolite binds to liver cells, resulting in the characteristic centrilobular hepatic necrosis seen in acetaminophen overdoses.[149–152]

Complication of Pregnancy

CASE 5-5, QUESTION 2: How does B.W.'s pregnancy change the management of her acetaminophen ingestion?

Pregnancy does not alter the initial approach to the assessment or treatment of potentially toxic ingestions, and assessment should focus initially on the mother.[153,154] Overdoses during pregnancy are often associated with attempted abortions, depression, prior loss of a child or children, potential loss of a lover, or economic reasons.[131,132,153,154] Intentional ingestions of analgesics, prenatal vitamins, iron, psychotropic agents, and antibiotics account for 74% of the overdoses during pregnancy.

The fetus is at risk when the mother overdoses on acetaminophen because acetaminophen crosses the placenta. The fetal liver can oxidize acetaminophen to its hepatotoxic metabolite by 14 weeks of gestation.[151] However, the fetal liver has only about 10% of the capability of the adult liver to metabolize acetaminophen. The fetal liver can conjugate acetaminophen with both glutathione and sulfate, but detoxification by glutathione conjugation appears to be decreased.[155,156]

In studies of maternal acetaminophen toxicity, most of the pregnant women survived without damage to themselves or their babies. However, there were also maternal and fetal deaths as a result of overdose.[155,157] Acetaminophen overdoses during pregnancy did not appear to increase the risk for birth defects or adverse pregnancy outcomes unless the mother suffered severe toxicity, emphasizing the need to treat the mother promptly.[149,155]

Gastrointestinal Decontamination

CASE 5-5, QUESTION 3: Should GI decontamination be initiated for B.W.? Justify your rationale.

B.W.'s acetaminophen ingestion occurred 8 hours ago; therefore, the drug is likely to be totally absorbed, and no GI decontamination should be initiated.

Estimating Potential Toxicity

CASE 5-5, QUESTION 4: How should the potential toxicity of the acetaminophen ingestion be assessed in B.W.?

Acetaminophen toxicity results from ingestions greater than 150 mg/kg or more than 7.5 g total in adults. However, serum acetaminophen concentrations better predict acetaminophen-induced hepatotoxicity than the dose of acetaminophen acutely ingested.[158,159] The Rumack–Matthew nomogram is used in the United States to assess the potential for hepatotoxicity from acute overdoses of acetaminophen.[160,161] The treatment line is defined by a serum acetaminophen concentration of 200 mcg/mL at 4 hours after acetaminophen ingestion and 30 mcg/mL at 15 hours after ingestion on a semilogarithmic graph.[152] Many prefer to be more conservative and use the bottom line of 150 mcg/mL at 4 hours to begin treatment as histories of ingestion are often inaccurate. The serum acetaminophen concentration is plotted on a graph against the time of ingestion.[159] The nomogram predicts the probability that the AST or ALT will be greater than 1,000 international units/L and can be used to guide therapy by indicating whether a specific acetaminophen concentration is in the toxic range.[162] The nomogram is useful only for acute ingestions because it underestimates the potential for toxicity in chronic acetaminophen ingestions. It should be noted that although the nomogram is used to plot acetaminophen concentrations for all patients, it has been validated only in healthy nonalcoholic adults.[152]

Acetaminophen Treatment Nomogram

CASE 5-5, QUESTION 5: When is the preferred time to measure a serum acetaminophen concentration?

Acetaminophen absorption generally is complete within 1.5 to 2.5 hours after ingestion of solid or liquid dosage forms.[159] The Rumack–Matthew nomogram is not applicable before 4 hours after ingestion because it is based on complete drug absorption.[159] Most clinical laboratories can complete their assays and report acetaminophen serum concentration results within 2 hours.

Stages of Acetaminophen Toxicity

CASE 5-5, QUESTION 6: What are the clinical signs and symptoms of acetaminophen toxicity?

Early detection of an acetaminophen overdose is difficult because there are no characteristic early diagnostic findings. Toxicity appears in stages that may overlap and are not clear-cut. About 30 minutes to 24 hours after ingestion, the patient may exhibit anorexia, nausea, vomiting, malaise, and diaphoresis that can easily be attributed to other causes. The second stage of acetaminophen toxicity occurs about 24 to 48 hours after ingestion and is the stage in which hepatotoxicity develops. Hepatotoxicity is universal by 36 hours after ingestion. An AST measurement is the most sensitive

---

measure of hepatotoxicity as AST abnormalities always precede evidence of actual liver impairment.[152,160,163]

In the third stage, 72 to 96 hours after ingestion, maximal liver dysfunction is evident with the return of anorexia, nausea, vomiting, and malaise. Symptoms can range from mild to fulminant liver failure with hepatic encephalopathy, coma, and hemorrhage. AST and ALT serum concentrations can be greater than 10,000 international units/L. There are also increases in bilirubin and INR measurements, as well as abnormalities in glucose and pH readings. Death, if it occurs, is usually a result of multiorgan failure or hemorrhage caused by hepatic failure. Most deaths occur 3 to 5 days after exposure. Patients who survive this stage go into recovery.[152,160,163]

Antidotes

CASE 5-5, QUESTION 7: What antidote for acetaminophen ingestion should be considered in B.W.? How does the antidote work, and when is it most effective?

Toxicity is determined by the results of a serum acetaminophen concentration measured at least 4 hours after ingestion.[159] N-acetylcysteine, or NAC, is the antidote for acetaminophen toxicity. NAC is a sulfhydryl donor that converts to cysteine, which is subsequently converted to glutathione.[149,160,162,163] NAC acts as a glutathione substitute and directly combines with the toxic acetaminophen metabolite, NAPQI, reducing it to a nontoxic cysteine conjugate.[163] NAC can also substitute for sulfation, which increases the nontoxic metabolism through that route as well. NAC increases intrahepatic microcirculation and is believed to possess hepatoprotective properties, showing some value even after liver damage has already occurred.[149,160]

Instituting therapy early with NAC is essential. When NAC is started within 8 to 10 hours of the ingestion, hepatotoxicity resulted in only 1.6% of cases. In patients who were started on NAC more than 10 hours after ingestion, 53% developed liver damage.[152,160]

Safety of N-Acetylcysteine in Pregnancy

CASE 5-5, QUESTION 8: Is NAC safe to use during pregnancy?

Acetaminophen overdose in pregnant women should be managed in the same manner as in nonpregnant patients.[155–157] If the life of the mother is not saved, the fetus will not survive (unless the child is near term and is emergently delivered). NAC therapy is not contraindicated in pregnant patients and might be helpful because it crosses the placenta and can protect the fetus from hepatotoxicity.[155,157]

NAC therapy appears to be protective for both mother and fetus.[152,155,158-160,162,163] When used as an antidote for acetaminophen overdose in pregnancy, NAC did not appear to cause toxic effects to the fetus.[149,152,155,157] The probability of fetal death was increased with the delay in NAC treatment after acetaminophen overdose.[152,156,160]

Route of Administration of N-Acetylcysteine

CASE 5-5, QUESTION 9: The 9-hour acetaminophen concentration in B.W. was 170 mcg/mL. By what route should NAC be administered?

This concentration of acetaminophen at 6 hours is above the treatment line on the Rumack–Matthew nomogram.[161] Because there was some delay from the time of ingestion to presentation at the ED and B.W. was already vomiting, it will be more difficult for B.W. to tolerate oral NAC. For this reason, IV NAC is recommended.

An FDA-approved sterile, pyrogen-free formulation of NAC is available as Acetadote.[164–166] The use of IV NAC is not completely risk-free because of a possible anaphylactoid reaction during the first dose of the IV NAC. The incidence of adverse reactions ranges from 14.3% to 23%. Asthmatic patients and patients with ectopy should receive the drug slowly and carefully, while being watched for symptoms of a reaction.[166]

A majority of the adverse reactions include nausea, vomiting, urticaria, flushing, and pruritus. Bronchospasm, angioedema, hypotension, and death have rarely occurred and must be carefully monitored when the IV route is being used.[167,168] Most reactions occur during or just after the first 15 minutes of the initial antidote infusion and appear to be dose related.[168] Because of the timing issue, the first dose of IV NAC is usually administered for 60 minutes instead of 15 minutes, even though a study comparing adverse reactions in the two infusion rates did not show clinically significant differences.[166,169]

Intravenous N-Acetylcysteine

CASE 5-5, QUESTION 10: How should IV NAC be administered to B.W.?

The FDA-approved IV NAC protocol is the same 20-hour dosing regimen used in

Europe, known as the Prescott protocol.[164,165,166] A 150 mg/kg loading dose of NAC in 5% dextrose is infused IV slowly for 60 minutes while watching for symptoms of a possible anaphylactoid reaction. This is followed by a maintenance dose of 50 mg/kg infused for 4 hours, and then followed with a 100 mg/kg dose infused for 16 hours. This regimen provides a total of 300 mg/kg NAC during the 20 hours after the loading dose.[166]

Oral N-Acetylcysteine

CASE 5-5, QUESTION 11: Once she is able to tolerate oral NAC treatment, what dosing regimen would be appropriate for B.W.?

The standard oral NAC protocol is based on the original clinical studies.[163] The loading dose of NAC is 140 mg/kg orally using either the 10% or 20% mucolytic solutions that were formulated for inhalation therapy. Seventeen additional maintenance doses of 70 mg/kg of NAC are administered at 4-hour intervals after the initial dose, for a total of 72 hours of therapy. This provides a total of 1,330 mg/kg NAC during 72 hours.[170] Because oral NAC contains a sulfhydryl group, the substance has a very disagreeable taste and smell (like rotten eggs) that commonly results in nausea and vomiting for the patient. To mask the unpleasant taste and odor, NAC is diluted to a concentration of 5% using a carbonated beverage or fruit juice.[163] Because the entire dose of oral NAC passes through the liver, high concentrations are produced, which is seen as an advantage of oral therapy.[164]

Shorter oral NAC regimens are currently being used based on the efficacy of IV therapy.[171,172] Short-course oral NAC follows the same 20-hour time course as IV NAC. Patients receive the usual 140 mg/kg oral loading dose of NAC, followed by 70 mg/kg every 4 hours for five additional doses (20 hours of therapy). Serum acetaminophen, liver function tests, and INR are repeated at 20 hours after the loading dose, which is after the fifth maintenance dose. If 20-hour liver function tests and coagulation studies are

---

normal and the acetaminophen level is less than the lower limits of detection, NAC can be stopped. A repeat set of liver function tests is recommended at 36 hours after ingestion. In other versions of the 20-hour NAC therapy, the dosage regimen is the same, but the laboratory studies are measured initially, and then at 16, 36, and 48 hours after ingestion.[172]

Efficacy of N-Acetylcysteine

CASE 5-5, QUESTION 12: Which route of NAC administration is more effective?

There is no proven evidence that one route of NAC administration is superior to the other.[161,164,173–175] Patient outcome after an acetaminophen overdose depends more on the time after the ingestion that treatment begins rather than on the route of administration of NAC. Patients who are started on NAC within 8 to 10 hours after ingestion, regardless of the route, rarely develop hepatotoxicity. Patients who present late or have a delay in the time of NAC treatment have higher rates of hepatoxicity.[150,161,164,170,174–176]

In one comparative study of IV NAC to oral NAC therapy, both were effective in reducing hepatotoxicity when therapy was initiated within 10 hours after ingestion. Vomiting delayed oral administration of the drug, but IV administration resulted in significantly longer delays in instituting therapy.[174] IV NAC avoids the problems of the vomiting patient, but oral NAC is safer. Oral NAC is associated with nausea and vomiting, whereas IV NAC is associated with bronchospasm, urticaria, and angioedema during administration.[149,160] In addition, oral therapy is much less expensive.[176]

Although the time of initiation of therapy is one of the key factors in reducing hepatotoxicity from acetaminophen ingestions, length of therapy has become another factor.[175,177] Because the duration of therapy with the IV formulation is 21 hours, patients with severe toxicity may be undertreated. It is essential that the patient be reevaluated at the end of the 21 hours to make sure that acetaminophen levels are not detectable and that liver enzymes are trending downward significantly. If there is still measurable acetaminophen and liver enzymes are still elevated, therapy with NAC must be continued.

Starting oral NAC may take less time to prepare than IV NAC therapy and is less expensive. If the patient presents early after an acetaminophen ingestion and does not have nausea and vomiting, oral therapy would be indicated. If the patient presents late (more than 10 hours after ingestion) with signs and symptoms of hepatotoxicity along with intractable nausea and vomiting, IV NAC should be instituted at once.[164,170]

Monitoring Efficacy of N-Acetylcysteine

CASE 5-5, QUESTION 13: How should the efficacy of NAC therapy be monitored in B.W.?

The effectiveness of NAC intervention in B.W. should be monitored by daily assessment of her acetaminophen concentration (as long as it is still measurable), AST, ALT, total bilirubin, glucose, and INR. The AST and ALT serum concentrations typically increase within 36 hours (range, 24–72 hours) after ingestion.[160,174] As the hepatic damage continues, the liver enzymes may peak at several tens of thousands units, even with NAC therapy. In most patients, AST and ALT begin to decline after 3 days and then return to baseline values.[160]

In a small number of patients, usually those who presented late after the ingestion, fulminant hepatic failure may develop. Symptoms of severe or persistent acidosis, coagulopathy, a significantly increased serum creatinine, and grade III to IV encephalopathy are consistent with fatal outcomes in patients with fulminant hepatic failure. Liver transplantation might be a consideration for these patients.[152,178–181]

Duration of N-Acetylcysteine Therapy

CASE 5-5, QUESTION 14: How long should NAC administration be continued?

The original NAC dosing protocol was based on an assumption that the half-life of acetaminophen was 4 hours. After five half-lives (20 hours), the acetaminophen should be metabolized and NAC could be discontinued. An NAC dose of 6 mg/kg/hour was determined to be necessary based on the rate of glutathione turnover relative to NAPQI production. To ensure that patients received an adequate NAC dose, the FDA recommended that this dose be changed to 18 mg/kg/hour for 72 hours.[182] This recommendation serves as the basis for the traditional 72-hour oral course of NAC therapy.

When using the traditional 72-hour oral course of NAC, therapy can be discontinued if the liver function tests are trending toward normal, other laboratory tests (i.e., coagulation studies, glucose, pH, bilirubin) are within normal ranges, and acetaminophen is no longer present in the serum. As long as acetaminophen is present, it can be metabolized to NAPQI and cause further toxicity.[162,171,182] Continued NAC will not be harmful to the patient and can be beneficial.

When using the shorter 20-hour course of oral NAC, if liver function tests and coagulation studies are normal and the 20-hour acetaminophen concentration can no longer be measured in the serum, NAC therapy can be stopped.[172] However, if 20-hour liver function tests or coagulation studies are abnormal, or if the 20-hour acetaminophen concentration measurement reveals acetaminophen still present in the serum, NAC therapy should be continued for at least another 24 hours.[173,174] Laboratory tests should be repeated every 24 hours, and the patient's progress must be monitored closely. If the patient is not improving, NAC should be continued until the patient recovers, receives a liver transplant, or dies.[152]

At this time, there is no consensus as to the best route of NAC administration, optimal dosage regimen, or optimal length of therapy.[160,164,182] There is consensus, however, that for optimal results, NAC therapy must be instituted within 10 hours after ingestion.[149,160,164,170,173,176] For patients who do not exhibit any signs of hepatotoxicity, shorter-course NAC therapy reduces the amount of NAC administered to the patient, decreases the quantity of laboratory tests, shortens hospital stay, and is less costly.[164,171,182]

N-Acetylcysteine Toxicity

CASE 5-5, QUESTION 15: How should the toxicity of NAC therapy be monitored in B.W.?

With the exception of vomiting, oral NAC is remarkably safe and has not been associated with toxicity.[149,161,164] Oral NAC must be retained for a minimum of 1 hour after ingestion to be successfully absorbed. If B.W. vomits within an hour after her oral NAC dose, the dose should be repeated. If she experiences protracted vomiting, administration of antiemetic drugs (e.g., ondansetron, metoclopramide) or placement of a duodenal feeding tube can improve GI tolerance.[164,183,184] If the patient cannot tolerate oral liquids, NAC therapy should continue via IV administration.

IV NAC therapy has been associated with anaphylactoid reactions in up to 14% of the patients. Although most reactions are not severe, bronchospasm, angioedema, and respiratory arrest have been reported.[149,160,164,182] Patients should be monitored for allergic and anaphylactoid reactions when NAC is administered IV. Most reactions can be avoided by infusing the NAC loading dose slowly for 60 minutes.[149,160,164]

Outcome of Patient B.W.

B.W. continued to have nausea and vomiting and had difficulty tolerating liquids. IV NAC was continued. An obstetrics consultation was requested to evaluate B.W.'s pregnancy. Fetal monitoring was instituted during her hospital admission. A sonogram was taken of the baby. Once B.W. saw her baby's image from the sonogram, her depressed mood seemed to lift. Approximately 36 hours after ingestion, her acetaminophen level was no longer detectable, and her liver function tests showed a mild elevation of her AST at 274 units/L and an ALT of 188 units/L. Her INR and total bilirubin values were normal at 0.7 seconds and 0.8 mg/dL, respectively.

B.W. was seen by a psychiatrist. She was scheduled for counseling and prenatal classes. B.W. seemed eager to attend the classes, and she talked enthusiastically about the baby when family members came to visit. Because of B.W.'s pregnancy, the decision was made to continue NAC for a full 72-hour course with the goal of protecting the fetal liver as much as possible. Six weeks later, she had a normal delivery of a healthy 6-pound, 1-ounce baby girl.

CONCLUSION

Unfortunately, there is no set formula to treat all poisoned patients. Each exposure is unique and patient-specific factors must be considered. Treatment of the poisoned patient often involves controversy because solid, evidence-based science to support a given decision is frequently lacking. When challenged with a poisoning exposure, consult with a poison control center by calling 1-800-222-1222, where consultation is available 24 hours a day in the United States.

End-of-Life Care

Victoria F. Ferraresi

	CORE PRINCIPLES	CHAPTER CASES
①	End-of-life care consists of palliative and hospice care. It is ideally introduced early in the disease progression to provide support to patients of all ages with a serious chronic or life-threatening illness. Medicare patients who enter a hospice program agree to relinquish their regular Medicare benefits as they relate to the terminal illness and accept the palliative rather than curative approach that will be provided by hospice. The hospice provides all care related to the hospice diagnosis under a managed-care model at a fixed reimbursement.	**Case 6-1 (Question 1)**
②	In 2008, the Hospice Conditions of Participation were updated to include a review of the medication profile as part of the initial assessment of new patients. The medication regimens of hospice patients should be continually reviewed and updated, with unnecessary, ineffective, or duplicative medications discontinued.	**Case 6-1 (Question 2)**
③	Patients near end of life can experience a number of distressing symptoms. These should be anticipated and treated in a timely manner that is acceptable to the patients and their families.	**Case 6-1 (Question 3), Table 6-3**
④	Well-trained pharmacists can improve medication management for hospice patients, while helping the hospice manage their drug costs.	**Case 6-1 (Question 2)**
⑤	Many barriers exist regarding pain management and the use of opioids.	**Case 6-1 (Question 4)**
⑥	Effective pain management uses a variety of approaches.	**Case 6-2 (Question 1)**
⑦	Pain and symptom management may at times require an aggressive approach.	**Case 6-3 (Questions 1–3)**

HOSPICE AND PALLIATIVE CARE

Terminology

Hospice care and palliative care are similar, but distinct, terms sharing the common belief that the relief of suffering is a long-standing, central, and fully legitimate aim of medicine. End-of-life care refers to both hospice care and palliative care. The basic principle of end-of-life care is to optimize the quality of life for the patient and family in the last weeks and months of life, as well as to provide support for the family beyond the end of life into bereavement.

Palliative care, which includes hospice care, is ideally introduced early in the disease progression to provide support to patients of all ages with a serious chronic or life-threatening illness. It can be provided concurrently with other treatments to cure or reduce disease or it can be provided independently. The word palliation, derived from the Latin word pallium (a cloak), has been defined as "treatment to reduce the violence of a disease." The World Health Organization and the National Consensus Project define palliative care as an approach that improves the quality of life of patients and their families who are facing a life-threatening illness, by preventing and relieving suffering through early identification and impeccable assessment and treatment of pain and other physical, psychosocial, and spiritual problems.[1–4] Palliative care

- Affirms life and regards dying as a normal process;
- Provides relief from pain and other distressing symptoms;
- Intends neither to hasten nor postpone death;
- Integrates the psychological and spiritual aspects of patient care;
- Offers a support system to help patients live as actively as possible until death;
- Uses a multidisciplinary team approach to address the needs of the patient and his or her family during the patient's illness; and
- Provides bereavement counseling when indicated.[3]

Hospice and palliative medicine became a recognized subspecialty of internal medicine in 2006, awarded by the American Board of Medical Specialties.[5] The Joint Commission offers an Advanced Certification Program for Palliative Care to recognize hospitals that provide high-quality palliative care services.[6]

Hospice, originally a place or way station for people making a pilgrimage, is considered both a philosophy of care and a place to deliver care. Hospice care focuses on the palliation of pain and other symptoms when active treatment to cure a terminal illness ends. Hospice care can be delivered in a building designated as a hospice, in the patient's home, or in a facility where the patient resides. As a programmatic model for delivering palliative care, hospice care provides an interdisciplinary team approach to the individualized symptom management (e.g., pain), as well as psychosocial, emotional, spiritual, and bereavement support for the patient and his or her family and caregivers during the last months of life.[7]

Hospice Care in the United States

According to estimates of the National Hospice and Palliative Care Organization, there were approximately 5,800 hospice programs in the United States in 2013. In that year, 42.9% of all deaths in the United States occurred under hospice care.[7,8] Hospices provided care for patients with various terminal illnesses (e.g., cancer [36.5% of all admissions], heart disease [13.4%], dementia [15.2%], and lung disease [9.9%]).[7] During the Medicare demonstration project (1980–1982), 93% of home hospice patients had cancer of various types.[9]

Adults younger than 34 years of age and pediatric patients account for less than 1% of the hospice population. Although pediatric hospice programs are growing, and more pediatric patients receive hospice services, the percentage of patients in this population has not increased from 2006 to 2013.[10] Regulatory, financial, cultural, and educational barriers play a role in diminished access to hospice care for pediatric patients.[10,11] States are required to offer hospice care (under Medicaid and other state programs as part of the Affordable Care Act) to pediatric patients with expanded benefits to improve coordination of care.[12]

About 84% of hospice patients were 65 years of age or older, and 41.2% were 85 years or older and in 2013, 87.2% of hospice patients received this care as a benefit provided by Medicare. Almost all (92.7%) hospice programs are certified by the Centers for Medicare and Medicaid Services to provide care to beneficiaries under the Medicare Hospice Benefit.[7]

The Medicare Hospice Benefit

The Medicare Hospice Benefit is funded from Part A (the hospital portion) of Medicare.[13] Patients are eligible for this benefit if, in the opinion of two physicians (i.e., patient's primary-care physician and hospice medical director), the natural course of their disease will result in death within 6 months. The hospice medical director determines the terminal diagnosis and any other conditions related to the terminal prognosis. Eligibility for hospice can continue beyond the initial certification if the hospice medical director recertifies eligibility at defined intervals, called certification periods. Other insurance payers generally follow this criterion. In electing this benefit, patients agree to relinquish their regular Medicare benefits as they relate to the terminal illness and related conditions and accept the palliative rather than curative approach that will be provided by hospice. This benefit links all care related to these diagnoses to the selected Medicare-certified hospice program, which coordinates and provides all care. The regulatory framework for the provision of hospice care under Medicare is defined in 42 CFR Part 418, Medicare and Medicaid Programs: Hospice Conditions of Participation.[13]

Hospice care is provided (and reimbursed) under Medicare at four levels, all of which can be modified at any time based on a patient's condition or caregiving needs:

- Routine home care (day-to-day care in the home)
- Continuous home care (when more skilled care in the home is required owing to symptom management or a caregiving crisis)
- General inpatient care (reimbursement for an inpatient stay in a hospital or skilled nursing facility related to symptoms that cannot be managed in the home)
- Inpatient respite care (up to 5 days in a skilled nursing facility) to give the caregiv a break or respite

Most care, consisting of pain and symptom management and assistance with activities of daily living, as well as psychosocial support, is provided to hospice patients at the routine level of care.

Patients may freely visit their primary-care provider (i.e., physician or nurse practitioner) for any reason, including reasons unrelated to their terminal illness. The primary-care provider will be paid directly by Medicare. Patients may choose to use their regular Medicare benefits for other unrelated illnesses; visits to providers for care or treatments unrelated to the primary hospice diagnosis are not limited or restricted. Patients may revoke their election of the Medicare Hospice Benefit at any time (e.g., end hospice care to pursue curative treatment or seek treatment outside the hospice plan of care). Patients may, at a later date, choose to return to hospice care or change to a different hospice program, without restrictions or loss of benefits.[13]

It is common for patients to be referred to hospice when death is imminent. Median lengths of stay have declined, from 37.1 days during the Medicare demonstration project (1980–1982) to 26 days in 2005 and to 18.5 days in 2013.[7,9,14] Approximately 34.5% of patients admitted to a hospice program in 2013 died or were discharged within 7 days.[7]

Hospice programs have historically received a fixed daily payment to provide all care related to the terminal diagnosis (e.g., medications, supplies, durable medical equipment, procedures, home health aides, provider visits, spiritual care, bereavement services). The reimbursement rates for the four levels of hospice care under the Medicare Hospice Benefit are established each summer for the following fiscal year, effective October 1.[15] A baseline reimbursement rate is set, along with an adjustment for wage differentials (the wage index) based on the local cost of living.[15,16] As an example, Table 6-1 shows reimbursement rates for the provision of routine home care in San Francisco, CA, and Jefferson City, MO, for fiscal year 2016 up to December 31, 2015. Historically, hospice reimbursement rates have been low and have not kept pace with rising costs. The total unadjusted hospice daily payment rate increased from \$146.63 per day to \$161.89 per day from 2011 to 2016 (approximately 2.1% per year).[15,17]

Table 6-1

Example of Hospice Daily Payment Rates for Routine Level of Care, 2016 Fiscal Year (October 1, 2015–September 30, 2016)[14,15]

	A Unadjusted Payment Rate (B 1 C)	B Nonlabor Portion	C Labor Portion	D Wage Index	E Adjusted Labor Portion (C 3 D)	F Total Daily Payment (B 1 E)
San Francisco, CA	$161.89	$50.66	$111.23	1.7260	$191.98	**$242.64**
Jefferson City, MO	$161.89	$50.66	$111.23	0.9366	$104.18	**$154.84**

Programs generally have high costs at the start of care because of personnel costs involved in the admission, assessment, and development of the initial plan of care, and obtaining medications, medical equipment, and medical supplies. High costs are also encountered nearer to the end of life, when new problems can appear and symptoms often intensify. The Centers for Medicare and Medicaid Services are implementing hospice payment reform beginning January 1, 2016, consisting of higher payments at the start of care (for days 1–60) and near the end of life via a service intensity add-on (SIA) to account for greater care needs during these periods.[15] It is anticipated that future reforms may include differing payments based on where the beneficiary resides (home versus a facility), including hospice care in Medicare Advantage plan coverage, or on the type of care provided, on quality outcomes, and on expanding the definition of what is related to the terminal prognosis.[18]

Drug costs continue to outpace increases in hospice reimbursement.[19] In 2014, overall drug spending in the United States increased 13.1% due primarily to increased prices for brand, niche ,and specialty drugs; increases in prices for compounded medications; and shortages resulting from industry consolidation. Prices for drugs for pain and inflammation increased by 15.7% in 2014. This is attributed by Express Scripts in part to new tamper-resistant formulations where there is no generic alternative.[19]

In reviewing hospice beneficiary use of Medicare Part D, CMS has reminded Medicare Part D Plans, pharmacies, and hospices that hospices are required to pay for virtually all care (including all related medications) for hospice patients (via Part A). An initiative to block Part D access to hospice patients was subsequently reversed by CMS with the clear expectation that hospices provide analgesics, antiemetics, laxatives, and anxiolytics and to coordinate drug coverage with the Part D plans.[20–22] Hospices are allowed to establish formularies, but if the hospice does not provide a related medication for any reason, the beneficiary may not use their Part D plan to obtain it. The result has been hospices paying for many more medications than in the past (i.e., covering medications used to treat rather than just palliate related conditions).

These variables (i.e., referrals to hospice later in the course of terminal illness, higher costs at the start of care, shortened lengths of stay, higher drug costs, providing more medications) have placed intense pressure on hospice programs to manage expenses. Because it is difficult to influence the time when patients are referred to hospice, the duration of time in hospice care, or the inherently higher costs when patients are first enrolled into hospice, the management of drug costs has taken a high priority in providing cost-effective hospice care.

Improving Patient Care and Managing Drug Costs

In 2008, the Hospice Conditions of Participation were updated to be more patient centered and outcome oriented.[13] Coverage of medications is mandated as described in 24 CFR §418.106 Drugs and biologicals, medical supplies, and durable medical equipment: ". . .drugs and biologicals related to the palliation and management of the terminal illness and related conditions, as identified in the hospice plan of care, must be provided by the hospice while the patient is under hospice care."

It also addresses medication management and the review of the medication profile specifying that "[t]he hospice must ensure that the interdisciplinary group (IDG) confers with an individual with education and training in drug management as defined in hospice policies and procedures and State law . . . to ensure that drugs and biologicals meet each patient's needs."

The regulations state that the comprehensive assessment must "take into consideration" the drug profile (24 CFR §418.54). This is defined as "[a] review of all of the patient's prescription and over-the-counter drugs, herbal remedies and other alternative treatments that could affect drug therapy" and is to include the following:

- Effectiveness of drug therapy
- Drug side effects
- Actual or potential drug interactions
- Duplicate drug therapy
- Drug therapy currently associated with laboratory monitoring

Although the regulations do not specify who is to perform the medication assessment, pharmacists are uniquely qualified to fill this role.

Well-trained pharmacists can improve patient care and positively affect the fiscal margins of hospice programs by discouraging inappropriate use of medications, establishing evidence-based formularies, promulgating prior authorization policies for specific targeted drugs, establishing policies for adhering to the use of generic drugs, and managing the quantities of medications to be dispensed. In addition to managing drug expenditures, pharmacists provide drug information both to patients and providers and work integrally with other members of the hospice health care team to improve the safe and effective use of medications.[23–37]

Referral to Hospice

ELIGIBILITY

CASE 6-1

QUESTION 1: M.P. is an 89-year-old woman referred to hospice for end-stage Alzheimer dementia. She lives in a residential care home for the elderly with a hired caregiver. Her husband has been unable to care for her at home for some time because she requires full assistance with all activities of daily living. She was recently hospitalized with aspiration pneumonia and a urinary tract infection (UTI) and completed a course of intravenous (IV) vancomycin and piperacillin/tazobactam. Her past medical history includes osteoporosis, coronary artery disease, chronic obstructive pulmonary disease (COPD), hypercholesterolemia, and hypothyroidism. She is not oriented to person, place, or date. Her speech is unintelligible or nonsensical. She cannot feed herself, but will eat the thick pureed food that is fed to her. She is bed-bound and incontinent of urine and stool. She is restless and irritable at times, especially at night. Her Palliative Performance Scale (PPS) is 30%. Weight is 112 pounds, decreased from 135 pounds a year ago, and a recent serum albumin is 2.2 g/dL. What criteria does M.P. meet for eligibility for hospice services under the Medicare Hospice Benefit?

Patients with chronic diseases (e.g., Alzheimer disease, Parkinson disease, stroke, heart failure, lung disease) can be sufficiently ill and debilitated to need custodial care, but might not be sufficiently ill to meet the definition of a terminal illness. This differentiation between terminally ill versus chronically ill requiring custodial care is important because to qualify for hospice services under the Medicare Hospice Benefit, patients must be at a stage where death is expected within the next 6 months. For cancer diagnoses, the presence

---

of widespread metastatic disease may make this prognosis more easily evident. However, for other chronic diseases, this is not as clear.

The Medicare fiscal intermediaries have issued criteria to assist in the determination of eligibility for hospice care, as well as criteria to meet a 6-month terminal prognosis for a number of diseases. These criteria, or local coverage determinations (LCDs), provide guidelines for meeting an overall decline in clinical status, for meeting non–disease-specific data to establish a baseline, for establishing the effect of comorbidities (e.g., renal failure, liver disease), and for the submission of documentation for having met criteria. Criteria have been established for patients with cancer and non-cancer diagnoses, and these criteria are used in the determination of eligibility for service and reimbursement.[38] Criteria for the noncancer diagnoses have been developed for amyotrophic lateral sclerosis, dementia as a result of Alzheimer disease and related disorders, heart disease, human immunodeficiency virus disease, liver disease, pulmonary disease, renal disease, stroke, and coma. Patients with cancer are eligible if they present with metastatic disease or progression from an earlier stage to metastatic disease with either a continued decline in spite of therapy or if they decline further disease directed therapy.

The determination of whether M.P. meets eligibility requirements for Medicare Hospice Benefits must be based on the established LCDs for dementia as a result of Alzheimer disease. These criteria include the following:

- Stage 7 or beyond, according to the Functional Assessment Staging Scale
    - Stage 7A: Can speak six or fewer intelligible words in a day or during an interview
    - Stage 7B: Speech ability limited to the use of a single intelligible word in a day or during an interview
    - Stage 7C: Cannot ambulate without assistance
    - Stage 7D: Cannot sit up without assistance
    - Stage 7E: Loss of ability to smile
    - Stage 7F: Loss of ability to hold head up independently
- Unable to ambulate without assistance
- Unable to dress without assistance
- Unable to bathe without assistance
- Urinary and fecal incontinence, intermittent or constant
- No consistently meaningful verbal communication; stereotypical phrases only or th ability to speak is limited to six or fewer intelligible words
- One of the following within the past 12 months: aspiration pneumonia, pyelonephritis, septicemia, decubitus ulcers (multiple, stages 3 and 4), fever (recurrent after antibiotic treatment)
- Inability to maintain sufficient fluid and caloric intake with 10% weight loss durin the previous 6 months or serum albumin less than 2.5 g/dL

The Palliative Performance Score (PPS) (Table 6-2) gradates the extent of disability and can be used to assist in the determination of hospice eligibility.[39] M.P. meets the previous criteria and is eligible for hospice because of her Alzheimer disease. She clearly is debilitated. She is unable to speak intelligently, cannot feed herself, is not oriented to time or place, is incontinent of urine and stool, has lost about 20% of her weight during the past year, has a serum albumin of 2.2 g/dL, and has a PPS rating of 30% (i.e., totally bed-bound, unable to do any activity, confused). In addition, she has a number of comorbidities, experienced a recent episode of aspiration pneumonia, and finished a course of antibiotic therapy.

MEDICATION MANAGEMENT

CASE 6-1, QUESTION 2: M.P. has no known allergies. Her current medications are memantine 10 mg twice daily, aspirin 81 mg once daily, alendronate 70 mg weekly, esomeprazole 20 mg daily, lovastatin 20 mg with dinner, megestrol 40 mg/mL 5 mL (200 mg) twice daily, levothyroxine 0.1 mg daily, multivitamin daily, beclomethasone metered-dose inhaler one puff daily, albuterol 2.5 mg/ipratropium 0.5 mg via nebulizer every 4 hours as needed for wheezing or shortness of breath, acetaminophen 325 to 650 mg every 6 hours as needed for mild pain or fever, olanzapine 5 mg at bedtime as needed for restlessness and aggressive behavior, milk of magnesia 30 mL daily for constipation, and a bisacodyl suppository 10 mg every 3 days as needed if no bowel movement. The hospice medical director has determined that the aspiration pneumonia, UTI, and COPD are related to M.P.'s terminal prognosis. What is your assessment of M.P.'s medication regimen? Which medications are the hospice required to provide, and which might be discontinued?

Hospices are required to provide (pay for) all medications related to the terminal diagnosis and related conditions within the hospice plan of care (POC). The POC is the individualized plan of treatment developed for each patient formulated at the start of care and updated regularly by the IDG. The Conditions of Participation mandate that the IDG be composed of a physician, registered nurse, social worker, and a pastoral or other counselor.[13] A registered nurse coordinates the implementation of the POC. Some hospice program IDGs have incorporated a pharmacist into the group to review medication issues.

The large array of medications being taken by M.P. is similar to the medication lists of many hospice patients. These patients are often elderly and have a long history of several chronic medical conditions for which they have been taking multiple medications. In most cases, the medication lists of patients who are admitted into a hospice program have seldom been reviewed, updated, or modified in light of the present medical situation. Admission to a hospice program represents a change in the level of care and is a most appropriate time for a review and reconciliation of all medications to ascertain the necessity of each, with the goal of optimizing efficacy and minimizing the potential for adverse effects, medication errors, and inappropriate costs.

Because M.P. is to be enrolled into a hospice program, her care should not be focused on curative treatments, but rather on the management of discomforting symptoms and on improving her quality of life in the time remaining. M.P.'s medications should be analyzed with the goal of simplification. Unnecessary medications should be discontinued and alternatives added to manage two or more symptoms concurrently. The following changes should be considered:

Acetaminophen. This analgesic is often helpful in relieving mild pain, particularly in immobile elderly patients. A trial of around-the-clock acetaminophen could be helpful.

Albuterol/ipratropium combination. The hospice program is required to pay for medications related to M.P.'s aspiration pneumonia and COPD because the hospice medical director determined that these conditions are related to her terminal prognosis. This combination inhalation formulation should be continued if she is able to participate in her nebulizer treatments and it improves her breathing. (See Chapter 19, Chronic Obstructive Pulmonary Disease.)

Alendronate. This bisphosphonate drug can be discontinued because the treatment of osteoporosis is not an important consideration at this terminal stage of her life nor is it in the hospice POC. Thus, hospice would not cover it. Furthermore, M.P. is bed-bound; alendronate should be ingested in the upright position, and patients should remain upright after taking the medication to decrease the risk of alendronate-induced esophageal irritation (see Chapter 110, Osteoporosis). Pain that she may experience from osteoporosis can be treated with analgesics.

Table 6-2

Palliative Performance Score (PPS) Version 2

PPS Level (%)	Ambulation	Activity and Evidence of Disease	Self-Care	Intake	Conscious Level
100	Full	Normal activity and work No evidence of disease	Full	Normal	Full
90	Full	Normal activity and work Some evidence of disease	Full	Normal	Full
80	Full	Normal activity with effort Some evidence of disease	Full	Normal or reduced	Full
70	Reduced	Unable to do normal job/work Significant disease	Full	Normal or reduced	Full
60	Reduced	Unable to do hobby/housework Significant disease	Occasional assistance necessary	Normal or reduced	Full or confusion
50	Mainly sit/lie	Unable to do any work Extensive disease	Considerable assistance required	Normal or reduced	Full or confusion
40	Mainly in bed	Unable to do most activity Extensive disease	Mainly assistance	Normal or reduced	Full or drowsy ± confusion
30	Totally bed-bound	Unable to do any activity Extensive disease	Total care	Normal or reduced	Full or drowsy ± confusion
20	Totally bed-bound	Unable to do any activity Extensive disease	Total care	Minimal to sips	Full or drowsy ± confusion
10	Totally bed-bound	Unable to do any activity Extensive disease	Total care	Mouth care only	Drowsy or coma ± confusion
0	Death				

Instructions: PPS level is determined by reading left to right to find a "best horizontal fit." Begin at left column reading downwards until current ambulation is determined, then, read across to next and downwards until each column is determined. Thus, "leftward" columns take precedence over "rightward" columns.

Aspirin. The low-dose aspirin is intended to decrease the risk of cardiovascular clotting. The aspirin will not increase M.P.'s comfort or quality of life. Although the aspirin would not be covered by her Medicare Hospice Benefit, it can be continued unless her primary-care provider prefers its discontinuation.

Beclomethasone. This patient is not functioning well cognitively (i.e., not oriented to time, person, or place) and would be unable to effectively time the inhalation of a breath to the actuation of her metered-dose inhaler. A systemic corticosteroid (e.g., prednisone) might improve her COPD symptoms and also improve her appetite and sense of well-being. The potential for adverse effects is modest with short-term corticosteroid use.

Bisacodyl, milk of magnesia. Constipation in patients with terminal illnesses is common, occurring in as many as 94% because of decreased gastrointestinal motility with advanced age, metabolic disturbances, decreased physical activity, lack of adequate fiber and fluid intake, and use of constipating medications (e.g., opioids, anticholinergics, psychotropic agents).[40–43] The milk of magnesia, with an occasional bisacodyl suppository, has been an adequate laxative regimen for this patient. If an opioid is later prescribed for M.P., a mild stimulant laxative (e.g., senna) can be added. Osmotic agents such as polyethylene glycol (PEG), oral sorbitol, or lactulose can be prescribed if needed. Mineral oil 30 mL daily is an option if the stool is hard; however, mineral oil should not be considered for M.P. because of her risk of aspiration. Bulk-forming laxatives should also be avoided in this population as they may not ingest adequate water to prevent a fecal impaction. In cases of refractory constipation, the use of methylnaltrexone bromide, an injectable opioid antagonist, can reverse opioid-induced constipation by antagonizing opioid effects within the gastrointestinal tract without affecting systemic analgesia.[44–46] This quaternary derivative of naltrexone does not cross the blood–brain barrier. Dosing is weight based; it is given subcutaneously as either 8 mg for patients weighing 38 to 62 kg (84–136 pounds) or 12 mg for patients weighing 62 to 114 kg (136–251 pounds) once a day. The most common adverse events are abdominal pain, flatulence, nausea, and dizziness.[43]

Esomeprazole. This proton-pump inhibitor would probably be unnecessary because alendronate-induced esophageal or gastrointestinal irritation would not be an issue subsequent to its discontinuation. However, if a proton-pump inhibitor is needed, nonprescription generic omeprazole or lansoprazole is preferred because they are more cost-effective.[47] If a patient such as M.P. cannot swallow intact tablets, a capsule formulation can be opened with the contents mixed with soft food and swallowed intact.

Levothyroxine. This thyroid medication should be continued until M.P. is no longer able to swallow. This medication, however, would not be covered under her Medicare Hospice Benefit, which is based on her Alzheimer disease, and was deemed not related to the terminal prognosis.

Lovastatin. Cholesterol-lowering agents are not necessary during the last 6 months of life and should be discontinued. Lovastatin would not improve the quality of life of M.P. at this stage of her terminal illness and would not be covered by her Medicare Hospice Benefit.

Megestrol. The progesterone derivative, megestrol, in doses of 400 to 800 mg daily, can substantially stimulate appetite.[48,49] If an undernourished hospice patient desires to eat more, the hospice may choose to provide an appetite stimulant. It is unclear whether stimulation of appetite in a cognitively impaired patient will result in weight gain or improved nutritional status. Because the benefits in this situation are unclear, the potential of adverse effects (e.g., venous thrombosis) of megestrol needs to be considered, especially in M.P., who is not ambulatory and had been taking low-dose aspirin for prevention of cardiovascular clotting.[50]

Memantine. Because the N-methyl-D-aspartate antagonist, memantine, has been modestly effective in improving performance in patients with moderate to severe Alzheimer disease,[51,52] but with decreasing effectiveness over time,[53] it is probably of limited utility for M.P. (See Chapter 108, Geriatric Neurocognitive Disorders.) It would be reasonable to discontinue M.P.'s memantine subsequent to discussion with appropriate hospice team members and M.P.'s family.

Multivitamins. Multivitamins and other nutritional supplements are unlikely to improve M.P.'s comfort or quality of life. The discontinuation of these drugs would simplify medication administration, decrease the potential for medication errors, and decrease costs.

Olanzapine. An antipsychotic (e.g., olanzapine, haloperidol, chlorpromazine) is often prescribed off-label to manage the agitation and confusion encountered by patients with dementia. Behavioral modifications can be tried (see Chapter 108, Geriatric Neurocognitive Disorders), but paranoid or delusional behavior may require drug therapy. At the time of admission to hospice, patients may be receiving atypical agents (e.g., olanzapine). Small doses of the first-generation antipsychotics, such as haloperidol and chlorpromazine, may offer a dual effect and be very useful in treating opioid-induced nausea and vomiting, although randomized clinical trials demonstrating efficacy are lacking.[54] They would be covered by M.P.'s Medicare Hospice Benefit. Chlorpromazine would be preferable when more sedation is desired.

SYMPTOM MANAGEMENT

The American College of Physicians has developed clinical guidelines, based on a systematic review of evidence and on a report by the Agency for Healthcare Research and Quality, to improve palliative care at the end of life. These guidelines provide strong recommendations for the regular assessment of patients at the end of life for symptoms of pain, dyspnea, and depression, and for therapies of proven effectiveness for these symptoms. For patients with cancer, these include the use of opioids, nonsteroidal anti-inflammatory drugs, and bisphosphonates for pain; tricyclic antidepressants, selective serotonin reuptake inhibitors, and psychosocial interventions for depression; and opioids for unrelieved dyspnea and oxygen for short-term relief of hypoxemia. The guidelines do not address other variables of palliative care at the end of life or the management of other matters (e.g., nutritional support) because the quality of evidence is limited rather than because other issues or symptoms are unimportant.[55] The National Consensus Project for Quality Palliative Care recommends the measurement and documentation of pain and other symptoms using available scales with timely assessment and symptom management acceptable to both the patients and their families as a preferred practice.[4]

CASE 6-1, QUESTION 3: As soon as the hospice admission and assessment is completed, the nurse in consultation with the IDG develops a plan for symptom management and orders a comfort kit for M.P. What are the components of this kit, and why is it useful?

Some hospices use a general comfort kit that contains specific medications to manage symptoms commonly encountered by most hospice patients, or they order medications to treat anticipated symptoms for a specific patient. These medications are placed in the home or facility where the patient resides. This facilitates the availability of medications to patients who encounter anticipated symptoms and is convenient when caregivers are instructed by the patient's primary-care provider to provide the medication to the patient. Patients living with cancer can encounter as many as 27 symptoms (median, 11), many of which occur together.[56] In one study, patients (n = 176) experienced an average of 6.6 to 6.8 distressing symptoms during the last week of life.[57] In general, the prevalence of each symptom is difficult to measure and demonstrates a high degree of variability. Pain (34%–96%), fatigue (32%–90%), and breathlessness (10%–95%) appear to be the most common in patients with a variety of terminal conditions, with the prevalence of pain in cancer patients reported as 35% to 96%.[58] Patients with terminal illnesses, including dementia as in M.P., also experience depression (3%–82%), anxiety (8%–79%), confusion (6%–93%), insomnia (9%–74%), nausea (6%–68%), constipation (23%–70%), diarrhea (3%–90%), and anorexia (21%–92%).[58] The disparity in symptom prevalence may be attributed to a host of variables (e.g., study design, patient population, underlying disease, inconsistent definitions, and where care was provided). The occurrence of symptoms, however, can vary significantly, even within the last week of life, and the need for frequent assessment of patients cannot be overemphasized. Morphine, lorazepam, haloperidol, prochlorperazine suppositories, and an anticholinergic agent are commonly ordered for hospice patients. Drugs that can palliate more than one symptom, such as morphine for pain or dyspnea, or haloperidol for agitation or nausea, are particularly suited to inclusion in a comfort kit.

Morphine. Every hospice patient should have a short-acting opioid available for the palliation of unrelieved dyspnea and pain. Although morphine can cause respiratory depression, small doses are very effective in controlling dyspnea by multiple mechanisms: vasodilation, reduced peripheral vascular resistance, inhibition of baroreceptor responses, reduction of brainstem responsiveness to carbon dioxide (the primary mechanism of opioid-induced respiratory depression), and lessened reflex vasoconstriction caused by increased blood PCO_2 levels. Opioids can also reduce the anxiety associated with dyspnea and might also act directly on opioid receptors present in the airways (Table 6-3).[59–64]

Hospice patients generally do not have IV access (i.e., an IV catheter) into which medications can be easily administered. As a result, medications are primarily administered orally and, occasionally, by sublingual, buccal, transdermal, rectal, or subcutaneous (if an infusion is warranted) routes of administration. When patients lose the ability to swallow near the end of life (or have a condition that precludes swallowing), the sublingual or buccal routes of administration are the most useful, especially if drugs are lipophilic. The use of orally disintegrating tablets (ODTs) may also be useful at this time. Morphine is hydrophilic, and although some of it might be absorbed across the mucous membranes, the primary clinical effect probably results from gastrointestinal absorption after the drug has trickled down the back of the throat.

Table 6-3

Treatment of Dyspnea at End of Life[59,64]

Nonpharmacologic methods
Pursed-lip breathing Upright position Relaxation Meditation Use of a fan or open window to circulate air over the face
Pharmacologic therapy
Systemic opioids (short-acting) in small doses given orally, sublingually, or via injection can be given every 1–2 hours as needed
Long-acting agents can be added to supplement the routine use of short-acting opioids
Inhaled opioids deliver medication via nebulization directly into the airway, avoiding first-pass metabolism, allowing use of smaller doses, theoretically minimizing side effects such as drowsiness. May cause local histamine release, leading to bronchospasm. Use nonpreserved sterile injectable products. More cumbersome

and expensive owing to use of nebulizer and nonpreserved parenteral products; evidence does not show that nebulized opioids provide greater benefit than nebulized saline
Agents: morphine 2.5–10 mg in 2 mL of 0.9% saline; hydromorphone 0.25–1 mg in 2 mL of 0.9% saline; fentanyl 25 mcg in 2 mL of 0.9% saline
Generally given every 2–4 hours as needed for breathlessness
Benzodiazepines are useful for the anxiety associated with breathlessness

Oral morphine sulfate, in a concentration of 20 mg/mL, is commonly packaged in a 30-mL bottle at the beginning of hospice care. This bottle of morphine can provide sixty 10-mg doses, and at this concentration, only 0.5 mL of morphine needs to be administered. Oxycodone or hydromorphone, in comparable adjusted doses, can be substituted for morphine when needed. There is no evidence demonstrating the superiority of any of these over the others in severe cancer pain.[65]

Lorazepam. A short-acting benzodiazepine (e.g., lorazepam 0.5 mg every 4 hours as needed) is useful for the treatment of anxiety. Patients, especially those with respiratory symptoms, can experience episodes of extreme anxiety near the end of life. Caution should be used to not overuse these drugs in the elderly because they can increase the risk of falling or cause paradoxical reactions and worsen delirium or restlessness.

Haloperidol. Small doses of haloperidol (e.g., 0.5–1 mg) are useful for the treatment of restlessness, delirium, or nausea and vomiting.

Prochlorperazine. When patients cannot take oral medications to manage nausea and vomiting, rectal suppositories of prochlorperazine are often effective. Although it is necessary to consider the etiology of the nausea and vomiting, prochlorperazine is generally a good initial agent.

Anticholinergic agent. As death approaches, patients can have difficulty in clearing pharyngeal secretions and, as a result, generate a sound commonly known as a death rattle.[66] Although patients are often unconscious at this point, this sound can be very distressing to those nearby. An anticholinergic agent (e.g., glycopyrrolate, hyoscyamine, scopolamine, atropine) can be administered in an attempt to prevent these pharyngeal secretions from forming. Patient positioning and gentle suctioning can remove secretions already present. This treatment modality is usually initiated after the patient has become obtunded; if begun too early, patients might develop problems with thickened bronchial or pulmonary secretions, tachycardia, delirium, dry mouth, urinary retention, or other adverse anticholinergic effects. However, efficacy is best if these agents are started earlier in the active dying process.[67] Glycopyrrolate, available in a tablet, injectable formulation and oral solution, is a good choice for an anticholinergic agent because it minimally crosses the blood–brain barrier. The 1-mg tablets could be crushed and placed under the tongue every 8 hours. Hyoscyamine is available as oral tablets, ODT, oral sustained-release tablets, sublingual tablets, oral liquid, oral solution, and injection. Either the ODT, sublingual tablets, or oral solution of hyoscyamine can be given in a 0.125- to 0.25-mg dose sublingually every 4 hours as needed. Scopolamine transdermal patches have a slow onset of action (blood levels are detected 4 hours after application)[68] and are of limited utility in this situation. The oral or sublingual administration of atropine ophthalmic solution 1% is convenient to administer. Recent shortages and price increases have made it less cost-effective. Assuming that 20 drops is approximately equivalent to 1 mL, patients can be given 0.5 to 1 mg (1–2 drops) of the atropine ophthalmic solution orally or sublingually every 4 hours as needed. Families and caregivers must be instructed not to use this in the eye.

CASE 6-1, QUESTION 4: The hospice nurse for M.P. has difficulty finding oral morphine sulfate available from a pharmacy and difficulty in finding a pharmacy willing to accept a faxed prescription. Why is morphine so difficult to obtain, and how should the nurse manage this problem?

Providing relief for pain or other symptoms with opioids is often difficult owing to numerous barriers. Patients and caregivers are often fearful of opioids, or mistakenly believe these medications will cause addiction or hasten death.[69] Pharmacists can create barriers by not having opioids in the pharmacy, sometimes because of the fear of robbery, fear of investigation by drug regulatory agencies, or insufficient appreciation of the usefulness of opioids in pain management and palliative care.[70] Pharmacists who are inexperienced in providing service to hospice patients might not be knowledgeable about federal regulations governing the provision of controlled substances to hospice patients. Federal statutes, as well as most state statutes, permit prescriptions for Schedule II controlled substances for hospice patients to be faxed. According to the Code of Federal Regulations (21 CFR 1306.11) paragraph (g): "A prescription prepared in accordance with 1306.05 written for a Schedule II narcotic substance for a patient enrolled in a hospice care program certified and/or paid for by Medicare under Title XVIII or a hospice program which is licensed by the state may be transmitted by the practitioner or the practitioner's agent to the dispensing pharmacy by facsimile. The practitioner or the practitioner's agent will note on the prescription that the patient is a hospice patient. The facsimile serves as the original written prescription for purposes of this paragraph (g) and it shall be maintained in accordance with 1304.04(h)."[71]

The process of ordering controlled substances for use by hospice patients at home can take many hours, and sometimes as much as an entire day. Hospice providers should anticipate possible difficulties when placing orders for Schedule II controlled substance medications. M.P.'s nurse should take the time to address any concerns M.P.'s caregivers and family may have about these medications (i.e., how they may affect her, any worries about addiction, side effects) and allow ample time to order them so that symptoms can be managed as they develop.

CASE 6-2

QUESTION 1: G.G., a 40-year-old woman, is admitted to hospice with stage IV ovarian cancer, metastatic to her pelvis, liver, and lungs. She was diagnosed after many months of nonspecific complaints of gastric distress and bloating. On laparotomy, she was evaluated as stage III and underwent a total abdominal hysterectomy and bilateral salpingo-oophorectomy and tumor debulking at that time. She has undergone subsequent chemotherapy and repeated tumor debulkings. In the past 6 months, her weight has decreased from 175 pounds to 153 pounds (she is 62 inches tall). Her primary complaints are constant nausea, constipation, and gripping abdominal pain, which she characterizes as burning and twisting. She quantifies the pain as 8 of 10 (on a 0-to-10-point scale) and describes the pain as one that moves into her groin and leg. Her family is unhappy about the drowsiness she experiences from her medications; they believe she is overmedicated. She is starting to have difficulty swallowing. She has no known allergies. Her current medications include fentanyl transdermal system 75 mcg/hour every 72 hours, extended-release morphine sulfate capsules 50 mg three times daily (usually intended for once-daily administration), docusate sodium 250 mg daily, lansoprazole 30 mg daily, and lorazepam 0.5 mg every 4 hours as needed for nausea and anxiety. What is the most accurate assessment of her pain management regimen?

G.G. is currently using two long-acting opioids (i.e., fentanyl transdermal, sustained-release morphine which is being dosed too frequently), but is still unable to achieve relief of her pain, which is probably neuropathic pain (described as burning and twisting). It is estimated that up to 39% of patients with cancer pain have neuropathic pain.[72–74] This may be caused by tumor growth around nerves, postoperative nerve damage, chemotherapy-induced neuropathy or following radiation therapy. Opioids alone may be of limited value or may require higher than usual dosing.[72] The addition of adjuvant analgesics such as antidepressants, anticonvulsants, and local anesthetics play an important role in treating neuropathic pain (see Chapter 55, Pain and Its Management).

The use of two long-acting agents is duplicative and should be replaced with one opioid. Methadone may be a better long-acting agent for G.G. because it has activity against neuropathic pain (see Chapter 55, Pain and Its Management) and can reduce the amount of medication she uses. Methadone affects the reuptake of serotonin and norepinephrine, and blocks the NMDA receptor.[75] Studies, however, do not show methadone to be superior to other opioids.[76] Advantages for G.G. include long half-life, high bioavailability, excellent absorption across mucous membranes, lack of active metabolites, and lower cost. Methadone liquid is long-acting which may be useful when patients lose the ability to swallow as death approaches. Disadvantages in using methadone are its long and variable elimination half-life, drug–drug interactions, prolongation of the QTc interval, and the variability of dosing equivalence with other opioids. Dosing methadone is complex and should be undertaken by experienced clinicians.[76,77]

When converting fentanyl and morphine to methadone, the following should be considered: (a) patient adherence and ability to follow prescription directions, (b) use of an appropriate conversion formula, (c) converting a transdermal formulation of fentanyl to an oral opioid formulation, and (d) a supplemental opioid for breakthrough pain.

Because of its long and variable elimination half-life, the dose of methadone should generally be adjusted only once every 4 to 6 days, and patients must be able and willing to precisely follow directions for its use. The methadone prescribing information should be used for the conversion, with a general rule of thumb being that the initial methadone dose should not exceed 30 mg (Table 6-4).[78,79]

New safety guidelines recommend electrocardiographic monitoring prior to and during methadone use[80;] the need for this is terminally ill patients should be balanced by life expectancy and goals of care. Caution should be used in patients with electrolyte abnormalities (hypokalemia or hypomagnesemia), impaired liver function, heart disease, prolonged QT syndrome, or the use of other QTc-prolonging drugs (e.g., amiodarone, azithromycin, citalopram, fluconazole, haloperidol, ondansetron).[81]

Once the conversion is made, the calculated dose is adjusted and the dosing interval is set at every 12, 8, or 6 hours, based on patient age, previous use of opioids, and current clinical status. Clinical judgment is vital in individualizing a regimen for each patient based on his or her needs.

Before calculating the conversion to methadone for G.G., an important consideration in patients using transdermal fentanyl is an assessment of its absorption.[82] Fentanyl from the transdermal system is absorbed through several layers of the skin and deposited in the subcutaneous fat, from which it is absorbed into the systemic circulation. It is generally observed that transdermal fentanyl is not effective in very thin, cachectic patients. In those cases, the conversion would be made without including the fentanyl. The patch would be removed at initiation of the first methadone dose and supplemented with medication for breakthrough pain if needed. In patients using multiple patches, one patch can be removed every 3 days. Despite weight loss, G.G. (62 inches and 153 pounds) is not cachectic, and the fentanyl should be included when calculating the conversion of her current opioid dose to a comparable methadone dose. In this patient, her sustained-release morphine formulation (50 mg three times daily) is equivalent to 150 mg/day of oral morphine. Her fentanyl transdermal system 75 mcg/hour is equivalent to about 150 mg/day of oral morphine. Her total morphine equivalents per day are 150 mg plus 150 mg, or 300 mg. Using a 1:5 to 1:10 ratio (10%–20%) for conversion of morphine equivalents to methadone, the calculated dose of oral methadone for this patient should be 30 to 60 mg/day.

Table 6-4

Conversion of Oral Morphine Dose to Oral Methadone Requirement[78,79]

Total Daily Baseline Oral Morphine Dose (i.e., Dose of Morphine Equivalents) (mg)	Estimated Daily Oral Methadone Requirement (as % of Total Daily Morphine Dose)(%)
<100	20–30
100–300	10–20
300–600	8–12

600–1,000	5–10
>1,000	<5

Although G.G. is relatively young, has been using opioids for some time, and has severe pain (quantified at 8 of 10), a methadone dose of 20 mg every 8 hours (i.e., 60 mg/day) might be excessive. She should be treated with 15 mg of methadone every 8 hours (45 mg/day), and the dose increased, if needed, based on her clinical response. This smaller initial dose would accommodate for some incomplete cross-tolerance from the morphine and fentanyl and for any fentanyl that remains in her system for the next several days. Patients who have been on much higher doses of opioids, alternatively, can be converted during a period of several days (e.g., converting one-third of the previous daily dose of opioid every 3 days). This is an especially useful method for converting opioid doses for thin, cachectic patients who have been on multiple transdermal patches. A clinician should be in touch with G.G. frequently during the first several days after her conversion to methadone. A telephone call should be made 2 to 4 hours after the first dose to assess for efficacy and toxicity (primarily somnolence, confusion, or nausea) and then every 3 to 5 days. If pain relief with the first dose does not last for the entire dosing interval, it can be adjusted, or G.G. can be instructed to take a one-time extra dose of methadone.

An added benefit in changing to methadone for G.G. is a financial one for the hospice. Outpatient prescription prices for long-acting opioids are very steep and significantly add to hospice costs. The prudent use of methadone can improve overall pain management and keep costs in check. When methadone is not appropriate, generic extended-release morphine is a good second choice. Transdermal fentanyl should be reserved for patients who cannot take oral medication or for when there are significant compliance issues. Extended-release oxycodone should be used only when patients cannot tolerate morphine, have significant renal impairment, or have other contraindications to its use. By converting to methadone, G.G.'s daily cost for the opioid alone will decrease substantially, while still providing appropriate and effective pain management.

G.G. will also need a supplemental analgesic for breakthrough pain. Some practitioners use small doses of methadone, 2.5 mg or 5 mg, as often as every 3 hours. This is a good choice in a well-supervised (i.e., inpatient) setting with nurses familiar with the use of methadone. However, if caregivers treat methadone as if it were morphine, which is much more commonly used for breakthrough pain, the risk of overmedicating the patient is very real. This can have disastrous consequences, especially in frail, elderly patients. Because G.G. is not in an inpatient setting and has tolerated morphine well in the past, 30 mg or 1.5 mL of morphine 20 mg/mL can be prescribed to be taken every 2 hours as needed for breakthrough pain.

G.G. should also start a bowel regimen; the use of a stool softener alone is inadequate.[42] The nurse should perform a rectal examination to determine if stool is present in the rectal vault. An enema or suppository can be given if needed and then senna or PEG can be taken on a routine basis.

Aggressive Symptom Management and Palliative Sedation

D.V.'s drug regimen is unnecessarily complicated for a patient at home. It may be possible to simplify it by looking at each problem anew. His pain is poorly managed as evidenced by his complaint of pain intensity at 7 of 10 (on a scale of 0–10), the use of multiple opioids, and the use of excessive PCA boluses. Once an infusion with PCA dosing is started, there is no need to continue other long-acting opioids (i.e., transdermal fentanyl) or oral agents for breakthrough pain. The PCA doses are serving as the rescue doses for breakthrough pain, and pain relief should be titrated using this method alone. Once pain is well controlled, an oral long-acting agent can be considered if the patient is able to swallow. To do otherwise creates a chaotic approach. Patients reporting allergic reactions to opioids should be carefully asked to describe the precise nature of the purported allergic reaction. True allergies to opioids are rare; patients often refer to an adverse reaction as an allergy or have experienced an effect from the histamine release that is associated with opioids. Hydromorphone, especially injectable hydromorphone, is much more expensive and no more effective than morphine and is best reserved for use in patients who have a genuine allergy or intolerance to morphine.

CASE 6-3

QUESTION 1: D.V., a 35-year-old man with gastric cancer metastasized to the esophagus with periaortic involvement, is hospitalized. He was diagnosed 10 months ago, and his disease has progressed despite multiple courses of chemotherapy (most recently, irinotecan and cetuximab). A double-lumen, peripherally inserted central catheter line has been inserted. He has lost 65 pounds since diagnosis, weighs 150 pounds at 6 feet tall, and presents with abdominal pain, severe nausea, vomiting, obstipation (intractable constipation), and general malaise. D.V. describes his pain as a 7 of 10 in intensity and as "burning like a knife through my stomach." He uses 50 to 75 patient-controlled analgesia (PCA) bolus doses every 24 hours. He has no other medical problems. D.V. is referred to hospice care because he and his wife have agreed to stop chemotherapy and do not want to go back to the hospital. He states a history of allergic reactions to morphine, ondansetron, and diphenhydramine, although these reactions are not noted. He is presently receiving hydromorphone 2 mg/hour in an IV infusion with 1 mg PCA bolus dose every 5 minutes, hydromorphone 4 mg orally every 4 hours as needed for pain, fentanyl transdermal 275 mcg/hour every 3 days, ketamine 20 mg orally every 3 hours, senna two tablets twice daily, docusate sodium 250 mg twice, PEG 3350 17 g daily, lactulose 15 mL as needed for constipation, lorazepam 2 mg orally every 4 hours as needed for nausea or vomiting, metoclopramide 10 mg orally every 6 hours as needed for nausea or vomiting, promethazine 25 mg IV every 4 hours as needed for nausea or vomiting, baclofen 10 mg every 8 hours as needed for hiccups, and pantoprazole 40 mg once daily. What is your assessment of his medication regimen?

Although D.V. had been prescribed ketamine every 3 hours in the hospital, it is unrealistic to expect that this can be continued in the home setting. D.V. and his wife would probably be glad to discontinue it and replace it with an alternative because of his need to be dosed so often.

D.V.'s constipation is currently treated with multiple medications within the same therapeutic class. It would be more prudent to maximize the use of a single agent within a category, rather than using two products at less than the maximally recommended doses. D.V. can use a higher dose of senna (up to four tablets twice daily), and then, if necessary, continue to use the PEG 3350.

D.V. also takes multiple medications for his nausea and vomiting. Promethazine primarily blocks the histamine receptor and can be continued if there is a vertigo component to his nausea and vomiting. The injectable promethazine can be converted to suppositories for use at home. Ondansetron ODT can be a good option when patients or caregivers refuse to use suppositories. He had also been directed to take lorazepam for his nausea and vomiting; however, benzodiazepines are not effective antiemetics. They are given to manage the anxiety associated with nausea and vomiting and are particularly useful in managing the anticipatory

---

nausea and vomiting that is commonly encountered during chemotherapy administration. Metoclopramide can be useful for D.V.'s nausea and vomiting if his physical examination reveals hypoactive bowel sounds. It is also useful for treating hiccups, and the need for baclofen can be reassessed.

In patients who are terminally ill, suffering may continue despite maximal palliative efforts. As a result, practitioners continually encounter patients' requests for the ending of their lives because of overwhelming suffering. Clinicians may be averse to this practice both ethically and legally.[83–92] Although substantial numbers of clinicians can imagine situations in which assisted suicide would be acceptable, few are willing to actively participate in the ending of a patient's life.[93,94]

CASE 6-3, QUESTION 2: A few days after arriving home, D.V. asks his hospice nurse, "Can't you just give me something to end it all?" He has not been sleeping well, is tired of taking so many medications, and wants to alleviate the burden he feels he is imposing on his wife.

In a small number of patients, it may be desirable to reduce suffering by the thoughtful use of medications to induce sedation.[95–102] It is not appropriate to increase opioid doses to achieve the desired sedated state. Medications used successfully to induce sedation for these patients include benzodiazepines, barbiturates, and propofol, generally given in combination. Opioids are continued to manage pain and prevent withdrawal.

A trial of palliative sedation with intravenous midazolam could be initiated and managed by the hospice nurse at a rate of 1 mg/hour and gradually increased if needed to the desired effect.[88] For use in the home, compounded phenobarbital suppositories could be added if the desired effect is not attained with midazolam alone. Although palliative sedation has a small potential to shorten life, the need to relieve terminal agitation or other symptoms could justify this risk. Palliative sedation should only be initiated as a last resort in severe cases not responsive to other palliative measures, and only after thorough discussion of the important clinical and ethical issues with the patient, family, and other clinical team members.

Before considering palliative sedation, patients should be thoroughly assessed for insomnia, depression, pain, and other symptoms. Underlying reasons for insomnia should be explored and treated. Poor pain management is often the cause for considering palliative sedation. As many as 10% to 20% of patients with cancer may have pain that does not respond to standard systemic analgesics.[103] Interventional techniques, including the administration of spinal opioids and/or local anesthetics may be useful, but may not be practical to initiate for the actively dying patient at home.[104,105] In D.V., lidocaine 0.5 to 1 mg/kg/hour administered IV or subcutaneously might be useful to assist in the management of his severe neuropathic pain.[106–110] Lidocaine purportedly interrupts pain transmission by blocking sodium channels (see Chapter 55, Pain and Its Management).

CASE 6-3, QUESTION 3: Repeated increases in the hydromorphone infusion basal rate (he is now at 25 mg/hour) had little effect on managing D.V.'s pain, and his consistent use of up to 120 PCA attempts in 24 hours reflects his continued pain. He describes the intensity of his pain as 8 of 10. Before considering palliative sedation, what other therapeutic interventions can be implemented for D.V.?

D.V. was started on lidocaine 1 mg/kg/hour IV. A bolus dose was not given because of the short half-life of lidocaine. Overnight, his use of hydromorphone boluses dropped to one. He now reports his pain as 1 of 10 and that he slept through the night for the first time in months. During the next 2 days, the hydromorphone basal rate was tapered to 5 mg/hour. He did not experience any lidocaine toxicity, such as perioral numbness, metallic taste, or somnolence. D.V. continued on lidocaine, using no hydromorphone boluses for the next 2 weeks, until he died at home surrounded by his family.

Interprofessional Education and Practice

William W. McCloskey, Edith Claros, Carol Eliadi, and Beth Buyea

	CORE PRINCIPLES	CHAPTER CASES
1	The Interprofessional Education Collaboration (IPEC) developed a report by an expert panel that highlighted what they believed are the 4 core competencies of interprofessional education (IPE): (1) values and ethics for interprofessional practice; (2) roles and responsibilities; (3) interprofessional communication; (4) teams and teamwork.	**Case 7-1 (Questions 1)**
2	The IPEC report considers communication a key competency but can be negatively impacted by demographic and professional differences that may exist between healthcare professionals. To address this issue, the IPEC report encourages all team members to be willing to speak up in a respectful way if they have a patient-related concern.	**Case 7-2 (Question 1)**
3	Although one should understand what IPE is, it is also important to clarify what does not constitute IPE. Experiences on Advanced Pharmacy Practice Experience (APPE) rotations that are directed by someone from another profession that do not include sharing of responsibility for patient care are not considered IPE.	**Case 7-3 (Question 1)**
4	Early exposure to IPE enhances students' confidence in their professional value, supports their respecting the contributions of other professions, and better prepares them for providing patient care. These early experiences also increase the appeal of collaborating with other professions, reduce any negative stereotypical attitudes toward these other professions, and strengthen communication skills.	**Case 7-4 (Question 1)**
5	One element of an IPE model is understanding that different professions may vary in how they approach patient care. Team-based care means a shared responsibility for patient care on the part of all team members and should not be dominated by any one profession.	**Case 7-5 (Question 1)**
6	It is important to understand that IPE models can place in a variety of settings, such a classroom, laboratory, and a patient care setting. Regardless of the environment, IPE-related activities should represent a "real-world" experience.	**Case 7-6 (Question 1)**
7	Despite the progress made in advancing IPE over the past few years, some barriers to implementing it exist on different levels, from the institution/organization level down to the individual level. Overcoming these barriers is important in order to continue to work toward preparing	**Case 7-7 (Question 1)**

students to collaborate with other healthcare professionals.

Interprofessional education (IPE) is considered to be a major attempt to better prepare medical, pharmacy, nursing, and other health profession students to collaborate and deliver patient care as part of a team.[1] Despite the recent attention it has received, IPE is actually not new, and the idea behind it has been in existence for some time. The first phase was initially launched in the 1940s, and a second wave of IPE coinciding with a move to enhance primary care was described in the 1960s.[2] In the early 1970s, the Institute of Medicine (IOM) Report “Educating for the Health Team” addressed pharmacy as a component of the team as well as medicine, nursing, and dentistry.[3] However, there remains a concern that many practitioners, including pharmacists, are commonly trained in programs that are removed from other healthcare professionals. This educational separation could potentially have a detrimental effect on the beliefs and values that these practitioners may have on the contribution of other providers to patient care.[2] In 2003, the IOM addressed this matter in their report “Health Professions Education: A Bridge to Quality.”[4]

The report stressed incorporating interprofessional experiences into healthcare education and establishing core competencies for IPE. The 2003 IOM report states “all health professionals should be educated to deliver patient-centered care as members of an interprofessional team, emphasizing evidence-based practice, quality improvement approaches, and informatics.” These IOM recommendations generated the momentum for health professions to advance the need for IPE.[1] It is evident that with the increasing prevalence of chronic diseases and the complexities of delivering health care today, an interprofessional approach toward patient care is important.[2] In addition, new approaches to health care, including the Patient Protection and Affordable Care Act of 2010, have stimulated a movement toward team-centered health care, such as the patient-centered medical home (PCMH) concept which encourages interprofessional teamwork in providing primary care.[5,6] With the PCMH model, physicians share responsibility with nurses, pharmacists, social workers, and others to manage complex patient care cases.[7] The PCMH model puts the patient at the center of his/her health care and expands access and improves mechanisms for patient–provider communication, including the use of technology (e.g., email) for patients to interact with their healthcare provider.[7] Although studies have shown that collaboration of healthcare professionals can result in improved patient outcomes, more work needs to be done to examine the relationship between IPE and positive patient outcomes.[8]

The reader is encouraged to apply these concepts to subsequent chapters as many of the cases presented can be used as part of IPE activities. In addition, students are encouraged to apply these concepts to IPE activities at their own institution.

CORE IPE COMPETENCIES

CASE 7-1

QUESTION 1: You are enrolled in a IPE seminar with pharmacy, nursing, physician assistant, and medical students. Each week you will be assigned cases to work on in groups. Your initial impression is that these exercises are primarily designed to help foster teamwork, but are there any other areas that IPE helps develop as well?

The Interprofessional Education Collaboration (IPEC), a group representing schools of pharmacy, nursing, medicine, osteopathic medicine, dentistry, and public health convened an expert panel to develop core competencies for IPE. The expert panel report was originally published in 2011[5] and was recently updated in 2016.[6] The four major competencies that are highlighted in the report are as follows: (1) values and ethics for interprofessional practice; (2) roles and responsibilities; (3) interprofessional communication; and (4) teams and teamwork.[5,6] These competencies were identified in order to create a coordinated effort across the different healthcare professions to incorporate key content into their respective curricula and to guide curricular development. The competencies also provide a foundation for lifelong learning, as well as offer information to the different professions' educational program accrediting bodies that can be used to set common accreditation standards.[5,6]

Regarding the first competency, the IPEC report considers interprofessional values and ethics an important element of establishing a professional and interprofessional identity. These values and ethics are patient-centered and grounded in a shared purpose to providing patient care. Working in teams adds value by bring about patient/family and community outcomes that promote overall health, disease prevention, and treatment of disease. In addition to being patient-centered, competency in this area helps develop trusting relationships with patients, families, and other members of the healthcare team. There is also an expectation that one maintains competency in one's own profession relative to his/her area of practice.[5,6]

The second competency addresses the importance that the IPEC places on one understanding how professional roles and responsibilities complement each other in providing patient care and to advance the healthcare needs of patients and populations. It is this diversity of expertise that is the foundation of an effective healthcare team. Coordination of care occurs more effectively when each profession knows what the other can contribute to patient care.[5] Pharmacists should be able to effectively articulate to other team members what they can contribute to executing a treatment plan, especially when it comes to preventing and identifying any drug-related problems. Sharing roles has also been shown to enhance patient outcomes and reduce costs.[2] For example, a nurse, social worker, and pharmacist can collaborate to develop a discharge plan that reduces the potential for hospital readmission by addressing such issues as community resources that may be available for assistance, medication adherence, patient education, and healthcare provider follow-up.[2] The IPEC report notes that one should also understand the limitations of one’s abilities, knowledge, and skills as well, and engage in continuous interprofessional development to improve team performance.[5,6]

The IPEC report also considers communication a key competency, and the expert panel states that one should communicate with patients, families, and both healthcare and non-healthcare professionals in a responsive and responsible manner. Characteristics such as being available, being well-informed, showing interest, and being receptive are key aspects of this communication area as well. Listening and encouraging the input of other members are also important attributes for this competency. Presenting information in a manner that patients, families, and other team members understand can help enhance the safety and effectiveness interprofessional care.[5,6]

CASE 7-2

QUESTION 1: You are on a medical team that includes a very intimidating attending physician. Your team is evaluating a patient presenting with an upper respiratory tract infection. You note from the medical record that the patient is on warfarin. The attending physician directs the medical resident to order an antibiotic that you know may interact with warfarin and possibly increase the risk of bleeding. How should you communicate your concerns to the attending?

Communication can be negatively impacted by demographic and professional differences that may exist between healthcare professionals (e.g., older attending physician and younger pharmacist). To address this issue, the IPEC report encourages all team members to be willing to speak up in a respectful way if they have a patient-related concern. You should politely and very clearly explain to the attending what your concern is and provide evidence-based literature to support the nature and severity of the interaction. Despite the attending’s intimidating demeanor, failure to communicate the problem could possibly result in harm to the patient. Being able to provide and receive feedback with confidence helps promote team-based care.[5,6]

The fourth competency cited by the IPEC, teams and teamwork, means working together for a common shared goal for patient care. The IPEC report indicates that working in teams not only relates to shared problem-solving, but being able to constructively manage any disagreements that arise with other healthcare professionals as well and patients and family. Conflicts may occur when power is confused with expertise based on professional background. Staying patient outcome focused and addressing any potential conflict openly through shared problem-solving and utilizing effective communication skills can help establish a more effective team. The report also indicates that working in teams also means that giving up some professional autonomy. Healthcare teams function best when the knowledge and expertise of the different professions on the team are integrated to make patient care decisions.[5,6]

As a consequence of this shift toward teamwork, many healthcare profession-accrediting organizations, including pharmacy, nursing, and medicine, now incorporate interprofessional collaboration and teamwork as part of their standards.[9] Pharmacy school graduates, in addition to those from other healthcare professions, must be able to work effectively with other providers as part of a team. The basic principle of IPE is that if students from different healthcare professions learn together, they will be better positioned to work together in teams to provide optimal patient care.[10] As Brock and colleagues recently noted, “health care education must be more of a team sport.”[11]

IPE TERMINOLOGY

The terminology related to IPE can be confusing as interpretation of multidisciplinary, interdisciplinary, and interprofessional may differ in the literature.[2] The Centre for the Advancement of Interprofessional Education (CAIPE) is an organization based in the United Kingdom that promotes and develops IPE initiatives. CAIPE defines IPE as occurring “when two or more professions learn with, from, and about each other to improve collaboration and the quality of care.”[12] The term interdisciplinary is sometimes interchanged with interprofessional and may be the more appropriate term to use in those situations where individuals who are not health professionals (e.g., nursing aides) are part of the team.[2] However, the term multidisciplinary should not be confused with interprofessional. The former is simple and additive approach to patient care, with several healthcare providers providing independent services, and each responsible for their own specialty. As described earlier, IPE is a more coordinated approach in which there is an integration and collaboration to include the viewpoints of many different professions in order to optimize patient care.[2]

CASE 7-3

QUESTION 1: You are on an internal medicine APPE rotation and round with a patient care team that includes a medical student, nursing student, and dietetics student. The medical resident presents a case of an elderly patient recently admitted with worsening heart failure and determines what the treatment plan would be without actually involving anyone else on the team. Is your experience considered an example of IPE?

Although one should understand what IPE is, it is also important to clarify what does not constitute IPE. For example, students from different health professions learning the same topic in a classroom setting (e.g., pharmacology) without interacting and discussing the material as it pertains to their respective discipline are not considered IPE.[1] Nor is it IPE when a faculty member from another profession lectures pharmacy students unless that person incorporates some component on how the professions would interact in providing patient care.[1] Also, experiences on Advanced Pharmacy Practice Experience (APPE) rotations that are directed by someone from another profession that do not include sharing of responsibility for patient care are not considered IPE.[1] Consequently, the experience described in Case 7-3 is not considered IPE. Clearly the underlying theme of any IPE activity is that it should be a collaborative effort of students representing different professions.

INCORPORATING IPE IN THE CURRICULUM

CASE 7-4

QUESTION 1: In your first professional year in pharmacy school, you are in an introductory healthcare seminar course with other health profession students. A fellow classmate complains that she would prefer to be with only other pharmacy students until later in the curriculum. What are the possible benefits of having other healthcare students in an introductory-level course?

The goal of IPE is to develop knowledge, skills, and attitudes that result in interprofessional team competence.[9] This includes not only clinical skills but communication, conflict resolution, team building skills, in addition to respecting the roles and responsibilities of other health professions.[2] IPE is best when it is incorporated throughout the entire curriculum in a vertically and horizontally integrated fashion, in which collaboration, teamwork, and patient-centered care are introduced to students prior to their entering the professional phase of the curriculum.[9] It has been reported that early exposure to IPE approach enhances students' confidence in their professional value, supports their respecting the contributions of other professions, and better prepares them for providing patient care.[13] It has additionally been noted that early educational experiences within an IPE program increase the appeal of collaborating with other professions, reduce any potential negative stereotypical attitudes one may have toward these other professions, and enhance communication skills regardless of any specialized knowledge one may have.[14]

The pharmacy education accrediting body, the American Council for Pharmacy Education (ACPE), has included IPE in their 2016 Standards and Guidelines for Accreditation for the PharmD program.[15] The goal is to make sure that schools of pharmacy incorporate the IPE within the PharmD curriculum. Standard 11 of the 2016 ACPE Standards specifically covers IPE. In order to meet this standard, the

PharmD curriculum of a particular pharmacy school should prepare “all students to provide entry-level, patient-centered care in a variety of settings as a contributing member of an interprofessional team.”[15] The key elements of this standard include interprofessional team dynamics, interprofessional team education, and interprofessional team practice.

The interprofessional dynamics section of the standard addresses issues such as values and ethics, interprofessional communication, conflict resolution, and honoring interprofessional roles and responsibilities. The standard indicates that “these skills should be introduced, reinforced, and practiced in the didactic and Introductory Pharmacy Practice Experience (IPPE) components of the curriculum, and competency is demonstrated in the APPE practice settings.”[15]

The interprofessional team education and team practice elements of the standard concern working together to improve patient care. Team education can include simulation exercises where pharmacy students can collaborate with medical, nursing, and other health professions students to better understand the contributions that each makes to the healthcare team. Team practice encompasses providing direct patient care as part of a shared decision-making process. It includes face-to-face interactions with individuals from other healthcare professions that are designed to improve interprofessional team effectiveness.[15]

Despite its merits, not every student may be initially understanding or accepting IPE. There are validated methods to

---

evaluate an individual’s ability to accept IPE. The Readiness for Interprofessional Learning Scale (RIPLS) has been used a research tool to assess attitudes and readiness for IPE.[16] It is a 19-item questionnaire that is designed to evaluate three primary areas: teamwork and collaboration, professional identity, and roles and responsibilities. The Interdisciplinary Education Perception Scale (IEPS) is another tool that assesses attitudes toward IPE.[17] This scale is an 18-item questionnaire that contains 4 subscale measures: competency and autonomy, perceived need for cooperation, actual cooperation, and understanding the value of others. Assessment instruments such as RIPLS and IEPS have been used to measure the impact that IPE experiences may have on students’ pre-exposure acceptance and attitudes. Although these and some other tools may be useful for measuring change in behavior or attitudes concerning IPE, they do not assess the impact that IPE may have on patient outcomes.[2]

IPE MODELS

The creation of an effective model for IPE should start with the understanding that this is just the initial step in providing patient directed care.[2] An interprofessional environment helps students from one profession learning from individuals representing another discipline to better develop skills that will help improve their own professional specific skills and to more effectively work in team-based setting.[2] It is important that all representatives of a particular profession, including students and practitioners, be socialized to their own profession as well as to the interdisciplinary setting. There also needs to be a commitment that IPE be incorporated within the curricula of all programs within an institution to help sustain its viability for the future.[2]

In addition to other health profession students, pharmacy students should be considered essential to any IPE model. Pharmacists have not always been considered necessary on a healthcare team, and this needs to be addressed when developing IPE teams.[2] IPE teams should ideally include a pharmacy student, in addition to medicine, nursing, social work, and nutrition students.[2]

The stage of socialization within the specific profession must be considered when creating teams as well.[2] Socialization of healthcare students has been defined as “the acquisition of knowledge, skills, values, roles and attitudes of associated with the practice of that particular profession,” and can be exhibited by the language, behavior, and demeanor that are representative of that specific discipline.[2] It is important that a student maintains his/her professional identity when participating in an IPE models. Also when creating student teams, one should try balance them with regard to what point they are in their professional socialization and education.[2] A medical student who is in the 4th year of his/her program who is paired with less experienced nursing or pharmacy student may negatively impact learning of the other students if the medical student assumes a more dominant role.[2]

CASE 7-5

QUESTION 1: M.M. is a 65-year-old retired man who presented to his provider three days ago with complaints of increasing shortness of breath (dyspnea) upon exertion. He reports noting swelling in his ankles for months that has started to get worse over the past 2 weeks, making it difficult to wear his shoes on toward the end of the day and going up the stairs to his apartment. In the past week, he has had a decreased appetite, some nausea and vomiting, and tenderness in the right upper quadrant of the abdomen. He reports that he has not taken his medications in the past month because he didn’t think they were helping him. The patient lives alone with his dog in a small two-bedroom apartment on the second floor of a multifamily home. He has a daughter who lives in another state and who visits him during the holidays. The patient was hospitalized and treated for a diagnosis of exacerbation of CHF and is now being discharged home. A physician, nurse, social worker, and pharmacist are part of a discharge planning team working with M.M. How does the approach of the pharmacist to M.M.’s care differ from that of the other team members?

One element of an IPE model is understanding that different professions may vary in how they approach patient care. Medicine and pharmacy tend to focus on eliminating or “ruling-out” causes of a patient’s complaint, whether it is medical- or drug-related.[2] While the physician will focus primarily on the medical evaluation of

M.M., the pharmacist would determine whether any of his medications were causing any effects which may have contributed to his belief that they were not helping him. The pharmacist would also work with M.M. to develop a plan that would enhance adherence to his discharge medications. Some other members of the team, such as the nurse and social worker, may take a more holistic approach and address the patient from a broader perspective.[2] This would include considering any family or environment issues that may affect M.M.'s progress such as ability for self-care when living alone and not having a relative living close by. They could make arrangements to make sure M.M. has the proper support at home. The nurse can also educate the patient about the importance of adherence to proper diet and to recognize early signs and symptoms of exacerbation. Some professions such as social work or psychology tend to be more involved with the patient or family for a more prolonged period of time, particularly if change in behavior is warranted.[2] Another consideration with how different professions approach patient care is that medical students are typically trained to be decision-makers regarding clinical problem-solving, which has been a long-standing part of the culture of medicine.[18] As noted previously, team-based care means a shared responsibility for patient care on the part of all team members and should not be dominated by any one profession.

CASE 7-6

QUESTION 1: Your university has an IPE day where medical students, nursing students, pharmacy students, and physician assistant students work in teams on simulated patient cases using a manikin. Is this considered an appropriate strategy for delivering IPE?

It is important to understand that IPE models can take place in a variety of settings, such a classroom, laboratory, and a patient care setting. Regardless of the environment, IPE-related activities should represent a "real-world" experience.[2] Simulation activities (simulating a patient care setting) and case discussions in a seminar format, where participants can exchange information, are appropriate for the early professional education years. Students may also observe activities of health providers upon patient visits and reflect on the contributions of each to patient care. The patient care setting is more appropriate for students with more experience.[2] In addition to certainly being real world, it is more effective in developing the confidence and skills needed for students to function as part of the team. In this experiential setting, clinicians from multiple professions who are active and engaged as role models and mentors are critical to the success of the model.[2]

Bridges and colleagues describe three different practice models of IPE, representing a didactic program, a community-based experience, and an interprofessional simulation experience.[19] The didactic program focuses on developing interprofessional team building skills, understanding other professions, and how culture influences healthcare delivery. Students work in small groups and also engage in a community service project. There is also a clinical component where students from different professions form teams and attend a prescribed number of sessions at a practice site. The community model illustrates how collaboration by different professions can provide patient care services to many underserved individuals in their homes. Teams of students are assigned home visits in a manner so that they are exposed to a variety of family types (e.g., Medicaid family with multiple children, older adult living alone, hospice patient). Each team has a project that they present to their group at the end of the course. With the simulation model, students from different professions use simulation and not real patients to promote interprofessional teamwork. Even though there are a number of different strategies that may be used to deliver IPE, the common elements that lead to more successful experience include responsibility, assertiveness, accountability, coordination, communication, trust, respect autonomy, and cooperation.[19]

POTENTIAL BARRIERS TO IPE

CASE 7-7

QUESTION 1: Although IPE is considered important, are there any barriers to implementing it?

Despite the progress made in advancing IPE over the past few years, some barriers to implementing it exist on different levels, from the institution/organization level down to the individual level. Overcoming these barriers is important in order to continue to work toward preparing students to collaborate with other healthcare professionals.

On the institutional/organizational level, academic calendars and requirements may differ between various healthcare disciplines. Also the requirements for assessing students may differ between professions due to accrediting body standards, and the timing of when topics are covered within the degree program may not be consistent. Finding a common time for students to meet is often a challenge, and there may not be available classroom space available to accommodate the increased number of students. In addition, the curricula of the different professions may also provide little flexibility in terms of incorporating IPE into the curriculum, although mandates by accrediting bodies such as ACPE dictate that this needs to happen for some professions. There may not be an adequate number of faculties trained in the area of IPE, and there may be insufficient faculty development efforts to address this issue. Collaboration with IPE efforts also may be negatively affected by geographic separation between disciplines that may exist within the institution.[2,20] It is important that the institution's administration commits the necessary financial and other resources necessary to address some of these potential obstacles to IPE.

There may also be barriers to IPE at the individual level. Differences in attitudes that exist between heath care professions can impact the implementation of IPE. It has been shown that healthcare providers may have negative opinions of each other's clinical knowledge and ability.[21] Michalec and colleagues surveyed over 600 first-year students from 6 different professions, including pharmacy, assessing their perceptions and stereotypes of their own as well as other healthcare professions.[21] The students rated the six professions based on nine distinct positive attributes (academic ability, professional competence, interpersonal skills, leadership ability, ability to work independently, ability to be a team player, ability to make decisions, practical skills, and confidence). Although medicine rated highest for most of these attributes, they rated lowest for ability to be a team player, which is contrary to the mission of team-based health care. Compared to the other professions (nursing, occupational therapy, physical therapy, couple and family therapy), pharmacy and medicine also scored low on interpersonal skills, which is a negative when it comes to working with others. Granted these are only perceptions of students about other health professions before any interaction, but they may represent potential barriers to providing team-based patient care.

Faculty also need to understand the value of IPE so they can be actively involved in implementing any program at their institution. Faculty may resist IPE if it results in an increase in workload and causes time constraints.[1]

FUTURE OF IPE

The first challenge is to sustain the IPE momentum that has been developed over the past several years and to provide the necessary resources to support it.[22] Expansion of IPE is also been identified as a future goal.[23] Further opportunities for collaboration between professions need to be identified, and the education of healthcare students needs to advance to the point where team-based learning is the norm, and that improved patient care is achieved.[23] It is believed that in the future, students and faculty will have multiple opportunities to interact with others, and that these experiences will further commit them to work together to improve patient outcomes.

There are still a number of issues concerning IPE that need to be addressed. There needs to be more objective evidence on the impact of IPE on improving patient outcomes.[24] In addition, there are still questions concerning how much IPE is needed to achieve learner competence, where in the curriculum does IPE have the greatest impact and what are the most effective formats for delivering IPE.[24]

CONCLUSION

The traditional model of practitioners working alone to provide patient care can result in communication failures and is detrimental to patient safety. A care plan that utilizes teams of healthcare providers, including pharmacists, to coordinate patient care can optimize patient outcomes. IPE can lead to better understanding of the roles and responsibilities of team members, improved communication and more effective teamwork.[8] Table 7-1 summarizes some suggested criteria for an organization to be engaged toward IPE.

Table 7-1

Suggested Criteria for Engagement for Interprofessional Education

1. A well-known, observable, measurable IPE philosophy that permeates the organization.
2. Faculty from different healthcare professions working together to develop the learning experiences.
3. Students having integrated didactic and experiential opportunities to learn how to build teams and to collaborate, and how working together can improve patient care.
4. IPE learning experiences being incorporated into to the curricula as a requirement.
5. Competence demonstrated by students with a defined set of competencies such as those outlined by the Interprofessional Education Collaboration.
6. Organization infrastructure that fosters and supports IPE including faculty time to develop IPE and having collaborative activities across the various professions.

Dyslipidemias, Atherosclerosis, and Coronary Heart Disease

Barbara S. Wiggins and Pamela B. Morris

CORE PRINCIPLES	CHAPTER CASES
① The risk of atherosclerosis is directly related to increasing levels of serum cholesterol. Cholesterol, specifically lipoproteins, plays a central role in the pathogenesis of atherosclerosis. Thus, low-density lipoprotein cholesterol (LDL-C) is the primary target for intervention. The American College of Cardiology/American Heart Association (ACC/AHA) guideline and the National Lipid Association (NLA) recommend management for patients at high risk. This includes patients with atherosclerotic cardiovascular disease (ASCVD) as well as those with familial hypercholesterolemia (FH).	**Case 8-1 (Question 1)**
② Every patient with dyslipidemia should be evaluated for secondary causes of elevated LDL-C, non–HDL-C, or triglycerides (TGs). These causes may be related to concomitant medications or due to a clinical condition.	**Case 8-1 (Questions 2, 3), Table 8-5**
③ LDL-C goals and the thresholds for instituting therapeutic lifestyle changes (TLC) and pharmacotherapy are guided by the presence of clinical atherosclerosis or based on cardiovascular risk.	**Case 8-2 (Questions 1, 2), Case 8-3 (Question 1), Case 8-4 (Questions 1, 2)**
④ An adequate trial of TLC should be used in all patients, but pharmacotherapy should be instituted concurrently in high-risk patients and patients should be monitored for adverse effects.	**Case 8-2 (Question 2), Case 8-5 (Question 1)**
⑤ In most cases, statins are the medications of choice to treat high LDL-C because of their ability to substantially reduce LDL-C, ability to reduce morbidity and mortality from atherosclerotic disease, convenient once-daily dosing, and low risk of side effects. Management of these adverse effects is necessary in order to optimize benefit.	**Case 8-2 (Question 3)**
⑥ Statins are the agents of choice to reduce LDL-C with low risk of adverse effects. However, drug interaction knowledge is needed in order to optimize efficacy without compromising safety.	**Case 8-4 (Question 3)**
⑦ Patients with high TGs are at increased risk of acute pancreatitis. The primary goal in these individuals is to lower their TG levels with diet, exercise, weight reduction, and TG-lowering drugs such as nicotinic acid, fibrates, and omega-3 fatty acids.	**Case 8-5 (Question 2), Case 8-6 (Question 1)**

8 Combination drug therapy is often needed in patients with severe lipid abnormalities, higher risk individuals with lower LDL-C goals, or patients with multiple lipid abnormalities such as those with the metabolic syndrome who have a secondary target of non–HDL-C.	**Case 8-6 (Question 2)**

Dyslipidemias (one or more abnormalities of blood lipids) play an important etiologic role in the pathogenesis of ASCVD, including coronary heart disease (CHD), cerebrovascular disease, and peripheral arterial disease.[1] Successful lifestyle changes and pharmacologic management of dyslipidemias have been shown to reduce the risk of ASCVD events such as heart attack and stroke.[2–4] For cardiovascular disease prevention, the clinician estimates the individual patient's ASCVD risk with available risk assessment tools, determines the intensity of lipid-modulating therapy to match the patient's level of risk, and implements appropriate treatments to meet and maintain treatment goals.[5–8]

LIPID METABOLISM

Knowledge of lipid and lipoprotein metabolism is essential to understanding therapeutic targets for pharmacologic agents. Lipids are small molecules that function in the body's storage of energy, in cellular signaling, and as components of cell membranes. Cholesterol, an essential lipid, is the precursor molecule for the formation of bile acids (which are required for absorption of nutrients), the synthesis of steroid hormones (which provide important modulating effects in the body), and the formation and integrity of cellular membranes. However, excess cholesterol plays a central role in atherogenesis and subsequent atherothrombotic complications.

Cells derive cholesterol in two ways: by intracellular synthesis or by uptake from the systemic circulation. Within each cell, cholesterol is synthesized through a series of biochemical steps, many of which are catalyzed by enzymes (Fig. 8-1). The irreversible and rate-limiting step in cholesterol production is the conversion of β-hydroxyl-β-methylglutaryl coenzyme A (HMG-CoA) to mevalonic acid, which is catalyzed by HMG-CoA reductase. One of the most effective lipid-lowering therapies developed to date for managing dyslipidemias, HMG-CoA reductase inhibitors or statins, competitively interferes with the binding of substrate to this critical enzyme, thereby reducing the cellular synthesis of cholesterol. The biosynthesis of cholesterol in humans follows a circadian rhythm with maximum cholesterol synthesis occurring near midnight and minimum synthesis at midday.[9]

Free cholesterol is esterified to cholesteryl esters for intracellular storage by the action of the enzyme acetyl CoA acetyl transferase (ACAT). Two forms of ACAT have been identified. ACAT1 is present in many tissues, including inflammatory cells, whereas ACAT2 is present in intestinal mucosa cells and hepatocytes. ACAT2 is required for the esterification and absorption of dietary cholesterol from the gut. In theory, inhibition of this enzyme could reduce the absorption of dietary cholesterol, the secretion of cholesterol by the liver, and even the uptake and storage of circulating cholesterol in inflammatory cells in the arterial wall. Several inhibitors of ACAT have been developed; however, in clinical trials they did not appear to reduce atherosclerosis and were possibly pro-atherogenic.[10] It is unlikely that there will be any further development of this class of drugs for cardiovascular prevention.

TGs are lipids that serve as an important source of stored energy in adipose tissue. TGs are synthesized from three molecules of fatty acids esterified to a glycerol backbone. Phospholipids (PLs) are a class of lipids formed from fatty acids, a negatively charged phosphate group, nitrogen-containing alcohol, and a glycerol backbone. PLs are essential for cellular function and the absorption, storage, and transport of lipids in the circulation. They form the monolayer on the surface of lipoproteins which function to transport neutral lipids throughout the body. PLs are amphipathic with a hydrophilic head and hydrophobic tail and form a membrane bilayer of lipoproteins to deliver hydrophobic cargo (cholesterol and energy in the form of fat) to other organs. PLs are also secreted into bile to aid in the digestion and absorption of dietary fat and lipid-soluble nutrients from the diet. They stabilize proteins within the membrane, function as cofactors in enzymatic reactions, and participate in the oxidation of lipoproteins in the arterial wall (Fig. 8-2).

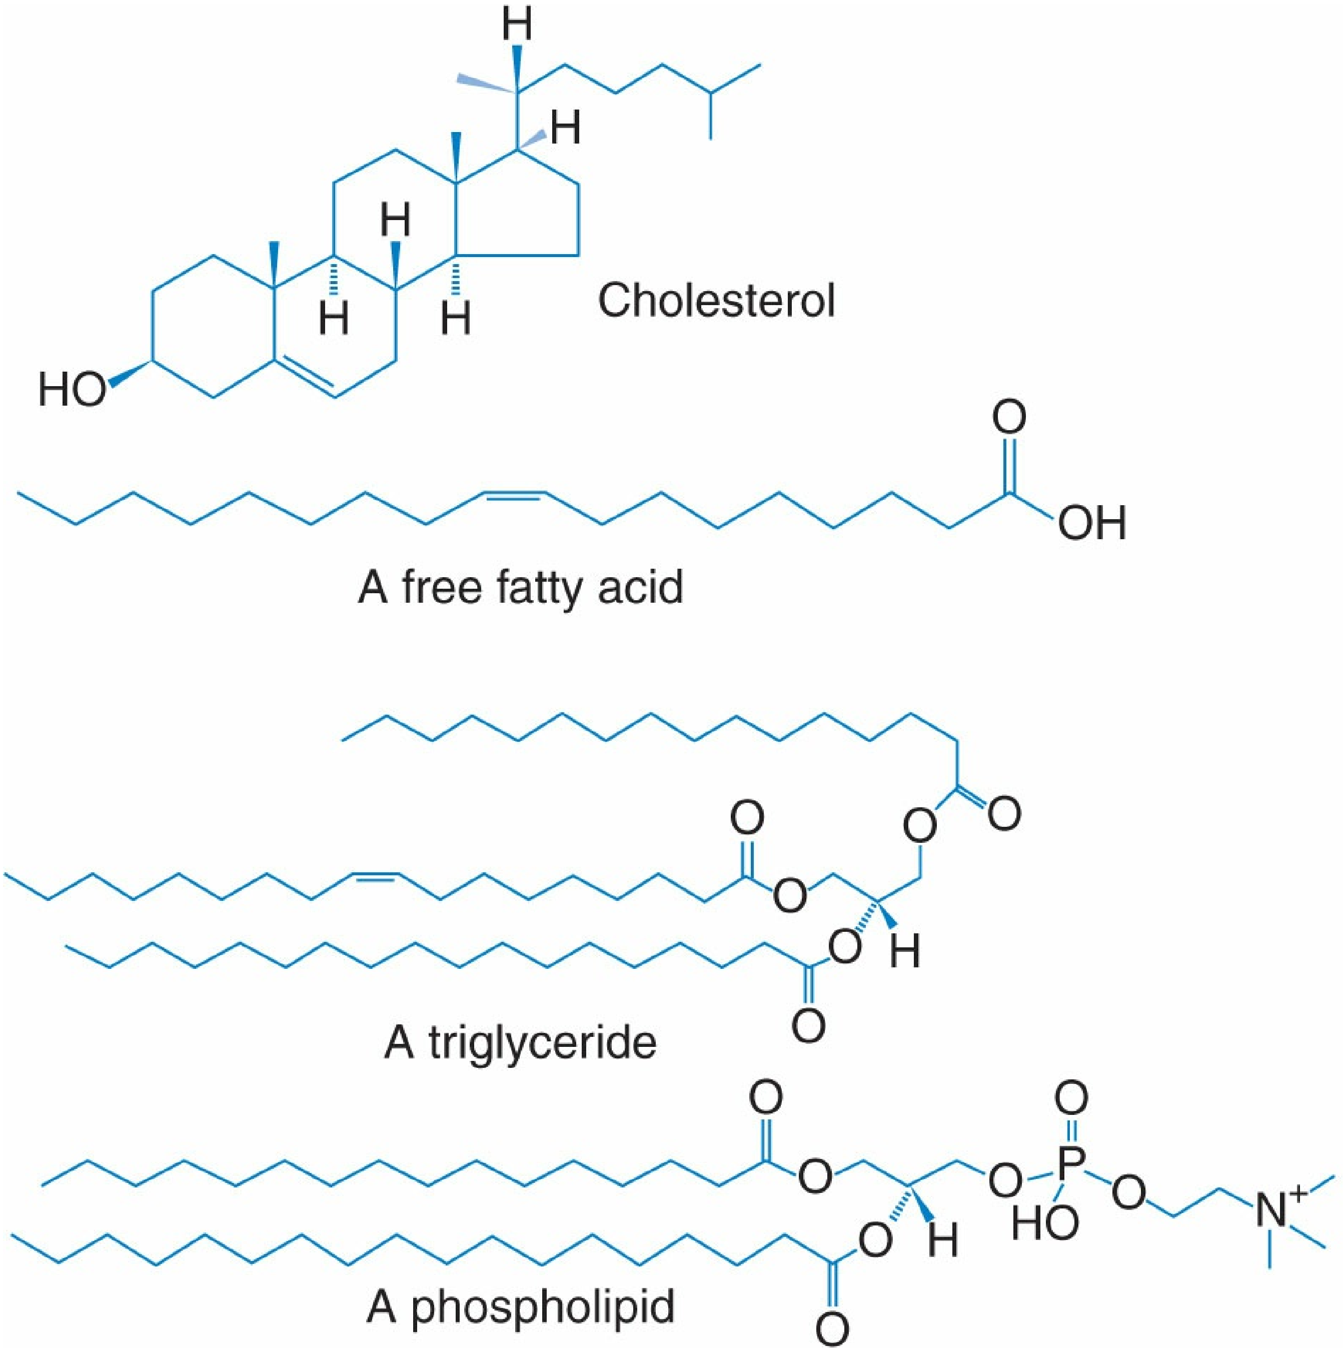

Figure 8-2 Chemical structure of lipids. At the top is cholesterol, followed by oleic acid. In the middle is a triglyceride comprised of an oleoyl, stearoyl, and palmitoyl chain attached to a glycerin backbone. At the bottom is a phospholipid.

Lipoproteins

Cells also obtain cholesterol by extracting it from the systemic circulation. The source of this cholesterol is the liver, where it is synthesized and secreted into the systemic circulation. As discussed above, cholesterol and other fatty substances are insoluble in water. Therefore, cholesterol, TGs, and PLs are packaged into water-soluble complexes called lipoproteins in the hepatocyte and enterocytes before being secreted into the aqueous medium of the blood. These lipoproteins contain an oily inner lipid core made up of cholesteryl esters and TGs and an outer hydrophilic coat made up of PLs and unesterified cholesterol (Fig. 8-3). The outer coat also contains at least one of a number of proteins known as “apoproteins,” which provide the ligand for interaction with receptors on cell surfaces, act as cofactors for various enzymes, and add structural integrity.

The three major lipoproteins found in the blood of fasting (10–12 hours) patients are very low density lipoprotein (VLDL), low-density lipoprotein (LDL), and high-density lipoprotein (HDL).[11] These particles vary in size, cholesterol and TG composition, and accompanying proteins (Table 8-1 and Fig. 8-4).[12,13]

VERY LOW DENSITY LIPOPROTEINS

VLDL particles are formed in the liver (Fig. 8-1). Free fatty acids are taken up by the hepatocyte where the enzyme diglycerol acyltransferase (DGAT) catalyzes TG formation from diacylglycerol and the coenzyme AcylCoA. The enzyme microsomal triglyceride transfer protein (MTP) lipidates apoprotein B by transfer of cholesteryl esters (CE) and TG to form VLDL, which is then secreted by the liver into the circulation. Inhibitors of MTP reduce production of VLDL and downstream IDL and LDL. One of these agents, lomitapide, is currently approved for the treatment of the homozygous form of FH.[14] DGAT inhibitors which reduce TG synthesis are currently under investigation for management of obesity and hypertriglyceridemia.[15]

VLDL particles normally contain 15% to 20% of the total blood cholesterol concentration and most of the total blood TG concentration. The concentration of cholesterol in these particles is approximately one-fifth of the total TG concentration; thus, if the total TG concentration is known, the VLDL-cholesterol (VLDL-C) level can be estimated by dividing total TGs by 5. Newly secreted VLDL particles are too large to migrate into the arterial wall and appear to play only a small role in the pathogenesis of atherosclerosis.

VERY LOW DENSITY LIPOPROTEIN REMNANTS

In the circulation the enzyme lipoprotein lipase (LPL) hydrolyzes TGs in VLDL particles. The removed TGs are converted to fatty acids and stored as an energy source in adipose tissue. As TGs are removed, the VLDL particle becomes progressively smaller and relatively more cholesterol rich. The particles formed through this process include small VLDL particles (called remnant VLDL), intermediate-density lipoproteins (IDL), and LDL (Fig. 8-5). Approximately 50% of the remnant VLDL and IDL particles are removed from the systemic circulation by LDL or apolipoprotein (apo) B-100/apo E receptors on the surface of the liver; the other 50% are converted into LDL particles by further hydrolytic action of hepatic lipase. VLDL remnant particles are found in the arterial wall, though in smaller numbers than LDL. Drugs that enhance the activity of LPL, such as the fibrates, increase hydrolysis of TG in VLDL particles and lower blood TG levels.

LOW-DENSITY LIPOPROTEINS

LDL particles are cholesterol enriched and carry 60% to 70% of the total blood cholesterol. LDL plays a central role in the pathogenesis of atherosclerosis and is the primary target of lipid-lowering therapy. Approximately half of the LDL particles are removed from the systemic circulation by the liver; the other half may be taken up by peripheral cells or deposited in the intimal space of coronary, carotid, and other peripheral arteries, where atherosclerosis can develop. The probability that atherosclerosis will develop is directly related to the concentration of LDL-C in the systemic circulation and the duration of exposure to elevated LDL-C levels; thus, the cumulative risk of ASCVD in men and women with hypercholesterolemia increases with age.

HIGH-DENSITY LIPOPROTEINS

HDL particles transport cholesterol from peripheral, lipid-rich inflammatory cells in the arterial wall back to the liver, a process called reverse cholesterol transport.[16] In epidemiologic studies HDL cholesterol (HDL-C) concentrations are inversely associated with the risk of ASCVD, presumably because cholesterol is being removed from vascular tissue and is not available to contribute to atherogenesis. In peripheral cells, the adenosine triphosphate binding cassette transporter A-1 (ABCA-1) and adenosine triphosphate binding cassette transporter G-1 facilitate the efflux of both cholesterol and PLs to apo A1 to form nascent HDL particles. Cholesterol acquired from peripheral cells by HDL particles is converted into an esterified form through the action of the enzyme lecithin-cholesterol acyl transferase (LCAT). HDL particles may either transport cholesterol directly to the liver through interaction with the scavenger receptor, SR-B1, on the surface of hepatocytes or transfer it to circulating remnant VLDL and LDL particles by the action of cholesterol ester transfer protein (CETP). CETP transfers cholesterol from HDL particles to VLDL and LDL in exchange for TGs, making the HDL particle less cholesterol rich. If the latter occurs, cholesterol may be returned to the liver for clearance from the circulation or delivered back to peripheral cells. Patients have been identified who have a deficiency of CETP and high plasma concentration of HDL-C which appears to be associated with a low incidence of CHD. Drugs that inhibit CETP can raise HDL-C levels and are being studied in long-term cardiovascular outcomes trial.[17]

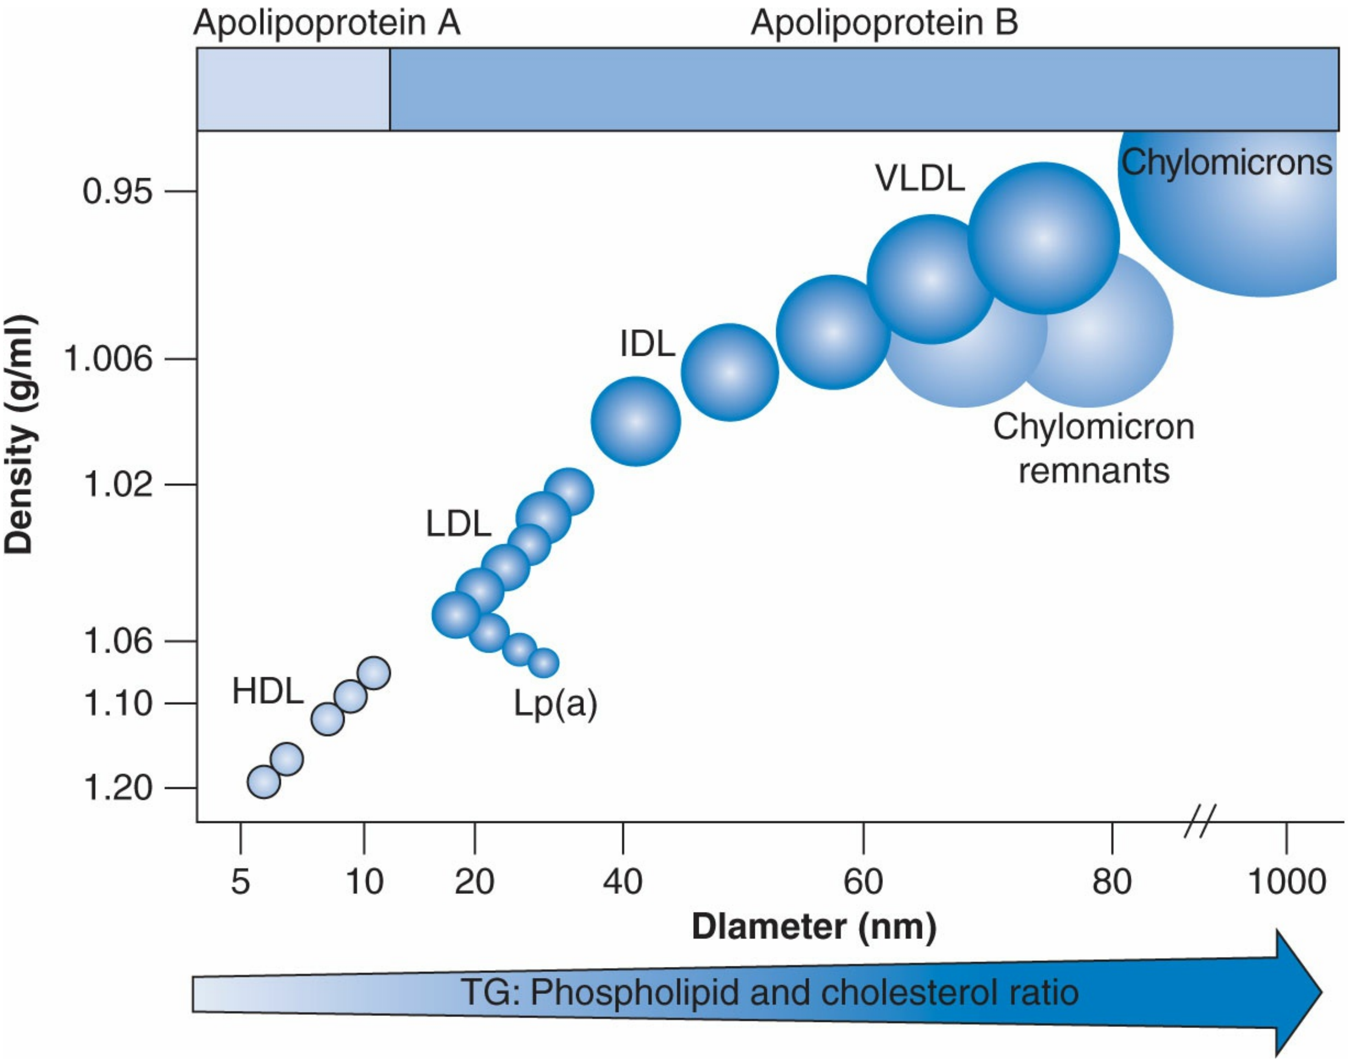

Figure 8-4 Relative lipoprotein sizes and densities.[13] Relative lipoprotein particle densities: In general, a subclass distribution of increased small LDL, decreased large HDL, and increased large VLDL particle size is most associated with increased CHD risk. NON–HIGH-DENSITY LIPOPROTEIN CHOLESTEROL

Though elevated LDL-C is most commonly associated with ASCVD risk, in some patients the assessment of LDL-C alone may underestimate the risk of events. Non–HDL cholesterol (non–HDL-C), calculated by subtracting HDL-C from TC, provides a measure of cholesterol carried by all potentially atherogenic particles, including VLDL, VLDL remnants, IDL, and LDL particles. Also, in the presence of postprandial hypertriglyceridemia the calculation of LDL-C may be inaccurate, whereas non–HDL-C is reliable when measured in the non-fasting state.

CHYLOMICRONS

Unlike the lipoproteins that transport cholesterol from the liver to peripheral cells and back (endogenous lipid transport), chylomicrons transport TGs and cholesterol derived from the diet or synthesized in the enterocytes from the gut to the liver (exogenous lipid transport) (Fig. 8-5, Table 8-1). Chylomicrons are large, TG-rich lipoproteins. As they pass through capillary beds on the way to the liver, some of the TG content is removed through the action of LPL in a manner similar to that described for hydrolysis of TGs from VLDL particles. In the rare individual who has LPL deficiency, chylomicrons are inefficiently metabolized and TG levels in the blood may become severely elevated (e.g., 1,000–5,000 mg/dL).

After a fatty meal the number of TG-rich chylomicron particles is elevated and TG levels rise. Following a 10- to 12-hour period of fasting, chylomicrons will be removed from the blood by LPL-mediated hydrolysis of TGs and removal of chylomicron remnants in the liver. TG concentrations measured in the fasting state reflect primarily TGs that are produced by the liver as well as TGs carried in VLDL and other remnant particles. For this reason, most patients are asked to fast before a lipoprotein profile is obtained. A blood sample that is rich in chylomicrons (and to a lesser extent VLDL particles) appears turbid; the higher the TG level, the more turbid the sample. If the sample from a patient with hyperchylomicronemia is refrigerated, chylomicrons will float to the top and form a frothy white layer, whereas smaller VLDL particles stay suspended below.

Apolipoproteins

Each lipoprotein particle contains proteins on the outer surface called apolipoproteins (Fig. 8-5, Table 8-1). These proteins serve four main functions: (a) they serve as major structural components of lipoproteins, (b) they serve as cofactors for activation of enzyme systems, (c) they act as ligands for binding to receptors on cell surfaces, and (d) they are required for assembly and secretion of lipoproteins.[15] Abnormal metabolism of apolipoproteins can

result in faulty enzyme activity or cholesterol transport and an increased risk of atherosclerosis. Clinicians may consider assessment of blood levels of apolipoproteins to evaluate dyslipidemic patients, especially those who have a family history of premature CHD. The five most clinically relevant apolipoproteins are B-100, C, E, A-I, and A-II.

VLDL particles contain apo B-100, E, and C (Fig. 8-5). The B and E proteins are ligands for LDL receptors (also called B-E receptors) on the surface of hepatocytes and peripheral cells. Linkage allows the transfer of cholesterol from the circulating lipoprotein into the cell through absorptive endocytosis and cellular uptake of the particle. Defects in these proteins reduce the ability of lipoproteins to bind with receptor proteins and may result in defective clearance of lipoproteins from the systemic circulation and increased levels of circulating cholesterol.

Apo C-II is a cofactor or activator of LPL. By activating LPL, apo C-II stimulates the hydrolysis of TGs from lipoprotein particles in the capillary beds. Deficiency of apo C-II may result in faulty TG metabolism and subsequent hypertriglyceridemia. Apo C-III downregulates LPL activity and interferes with the hepatic uptake of VLDL remnant particles. This leads to increased concentrations of small VLDL remnant particles, which are small enough to penetrate into the arterial wall and contribute to atherogenesis. Apo C-III is a marker of atherogenic dyslipidemia (elevated TGs, reduced HDL-C, near normal levels of LDL-C, and elevated LDL particle concentration), which is associated with an increased risk of ASCVD events. In addition, prolonged residence of VLDL and LDL particles in the systemic circulation results in the formation of small, highly atherogenic LDL particles and the atherogenic dyslipidemia (see below).[18]

Each VLDL, IDL, and LDL particle contains one molecule of apo B-100. Thus, the blood concentration of apo B-100 is an indication of the total number of VLDL, VLDL remnant, IDL, and LDL particles in the circulation. An increased number of lipoprotein particles and an increased apo B-100 concentration are strong predictors of ASCVD risk.[19] Remnant VLDL particles retain both apo B-100 and E during the delipidization process; LDL particles contain only apo B-100 (Fig. 8-5). Some patients have high levels of apo B-100 suggesting an increased number of atherogenic particles in the circulation, even though the LDL-C level is in the desirable range. These patients have an increased risk of atherosclerosis. Apo B-100 and the measurement of LDL particle concentrations by nuclear magnetic resonance spectroscopy are considered as recommended treatment targets by some guidelines for the management of dyslipidemia.[7,8]

HDL particles contain apo A-I, A-II, and C. Apo A-I is an activator of LCAT, which catalyzes the esterification of free cholesterol in HDL particles. Levels of apo A-I have a stronger inverse correlation with CHD risk than apo A-II levels. HDL particles that contain only A-I apolipoproteins are associated with a lower CHD risk than are HDL particles containing both A-I and A-II.[20]

Low-Density Lipoprotein Receptor

Cholesterol is taken up by peripheral and hepatic cells via binding of the ligands, apo B-100 and E, on circulating lipoproteins to cell-surface LDL receptors. The concentration of LDL receptors is mediated by intracellular cholesterol concentration. Synthesis of LDL receptors is stimulated by a low intracellular cholesterol concentration. Conversely, the concentration of cell-surface LDL receptors may be downregulated by the action of proprotein convertase subtilisin/kexin type 9 (PCSK9), which targets the LDL receptor for degradation within intracellular lysozymes.[21] Within the cell, the receptor protein is synthesized in the mitochondria and migrates to clathrin-coated pits on the cell surface. The LDL receptor may then bind to lipoproteins that contain apo E or B-100, including VLDL, remnant VLDL, IDL, and LDL. Because remnant VLDL and IDL particles contain both B-100 and E proteins, they may have a higher affinity for LDL receptors than do LDL particles, which contain only the B protein. Drugs that upregulate the synthesis of LDL receptors (e.g., statins), therefore, may increase the clearance of both VLDL remnant particles and LDL particles from the circulation. Thus, statins may reduce serum TG levels as well as cholesterol levels. Following binding of lipoproteins to the LDL receptor, the lipoproteins undergo endocytosis and are taken up by lysosomes, where they are metabolized into elemental substances for use by the cell. The cholesterol is transferred into the intracellular cholesterol pool. The LDL receptor may be returned to the cell surface, where it can bind with another circulating apo E- or apo B-containing lipoprotein.

ABNORMALITIES IN LIPID METABOLISM

Lipid synthesis and transport is complex with hundreds of possible steps that can malfunction resulting in a lipid disorder. However, there are only a few relatively common and important lipid disorders seen in clinical practice. The first two described subsequently, polygenic hypercholesterolemia and atherogenic dyslipidemia, are largely the result of an interaction between genes and lifestyle choices. Several prominent, but rarer, familial lipid disorders are subsequently described. Table 8-2 summarizes the characteristics of the most common lipid disorders.

POLYGENIC HYPERCHOLESTEROLEMIA

Polygenic hypercholesterolemia is the most prevalent primary disorder causing an increase in cholesterol. It is caused by a combination of environmental (e.g., poor nutrition, sedentary lifestyle) and multiple genetic factors. In patients with this disorder a diet high in saturated fatty acids can reduce LDL receptor activity, thus reducing the clearance of LDL particles from the systemic circulation. Patients with polygenic hypercholesterolemia have mild to moderate LDL-C elevations (usually in the range of 130–250 mg/dL), but no unique physical findings are usually present. A family history of premature CHD is present in approximately 20% of cases. These patients may often be effectively managed with dietary restriction of saturated fats and cholesterol and by drugs that lower LDL-C levels (statins, bile acid sequestrants (BASs), and ezetimibe).

Atherogenic Dyslipidemia

Atherogenic dyslipidemia is characterized by moderate elevations of TG (150–500 mg/dL, indicative of the elevated VLDL remnant particles), low HDL-C levels (<40 mg/dL), and mild to moderate elevations of LDL-C level.[22] These patients have increased concentrations of small, dense, cholesterol-poor LDL particles, non–HDL-

C, and apo B-100. Most commonly, patients have increased visceral adiposity and are hypertensive and insulin resistant.

In the presence of increased visceral adiposity there is impaired glucose metabolism and/or diabetes with increased mobilization of fatty acids from adipose cells to the systemic circulation. The excess of free fatty acids leads to increased TG synthesis and secretion of TG-rich VLDL particles by the liver. These TG-rich particles contain apo C-III, which inhibits the action of LPL, thus retarding lipolysis of TGs from VLDL particles. This results in an excess of TG-rich VLDL remnant particles.[23] CETP mediates the exchange of TGs from these particles with cholesteryl esters from HDL, resulting in VLDL remnant particles that are enriched with cholesterol (Fig. 8-6). TGs are also exchanged from VLDL remnant particles with cholesteryl esters from LDL particles. Thus, VLDL remnants become even more cholesterol-enriched and LDL particles become TG-enriched. The cholesterol-enriched, small VLDL remnant particle is atherogenic. TG-rich LDL undergoes lipolysis catalyzed by hepatic lipase to remove TGs, resulting in small, cholesterol-poor LDL particles (called small dense LDL) that are highly atherogenic. Lipolysis of TG-rich HDL results in low HDL due to excretion of lipid-poor apo A-I by the kidneys.

Table 8-2

Characteristics of Common Lipid Disorders

Disorder	Metabolic Defect	Lipid Effect	Main Lipid Parameter	Diagnostic Features
Polygenic hypercholesterolemia	↓LDL clearance	↑LDL-C	LDL-C: 130–250 mg/dL	None distinctive
Atherogenic dyslipidemia	↑VLDL secretion ↑ApoC-III synthesis ↓LPL activity ↓VLDL removal	↑TG ↑Remnant VLDL ↓HDL ↑Small, dense LDL	TG: 150–500 mg/dL HDL-C: <40 mg/dL	Frequently accompanied by central obesity or diabetes
Familial hypercholesterolemia Heterozygous	Reduction in functional LDL receptor, defective apo B, gain-of-function mutations PCSK9	↑LDL-C	LDL-C: 250–450 mg/dL	Family history of premature CHD, tendon xanthomas, corneal arcus
Familial hypercholesterolemia Homozygous	Absent LDL receptors, defective apo B, gain-of-function mutations	↑LDL-C	LDL-C: >450 mg/dL	Family history of premature CHD, tendon xanthomas, corneal arcus; affected individuals

	PCSK9			exhibit CHD by second decade of life
Familial defective apoB-100	Defective apoB on LDL and VLDL	↑LDL-C	LDL-C: 250–450 mg/dL	Family history of CHD, tendon xanthomas
Dysbetalipoproteinemia (type III hyperlipidemia)	ApoE2:E2 phenotype, ↓VLDL remnant clearance	↑Remnant VLDL, ↑IDL	LDL-C: 300–600 mg/dL TGs: 400–800 mg/dL	Palmar xanthomas, tuberoeruptive xanthomas
Familial combined hyperlipidemia	↑ApoB and VLDL production	↑CH, TG, or both	LDL-C: 250–350 mg/dL TGs: 200–800 mg/dL	Family history, CHD Family history, hyperlipidemia
Familial hyperapobetalipoproteinemia	↑ApoB production	↑ApoB	ApoB: >125 mg/dL	None distinctive
Hypoalphalipoproteinemia	↑HDL catabolism	↓HDL-C	HDL-C: <40 mg/dL	None distinctive

ApoB, apolipoprotein B; ApoC-III, apolipoprotein C-III; ApoE, apolipoprotein E; CH, cholesterol; CHD, coronary heart disease; HDL, high-density lipoprotein; HDL-C, high-density lipoprotein cholesterol; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; LDL-C, low-density lipoprotein cholesterol; TGs, triglycerides; VLDL, very-low-density lipoprotein.

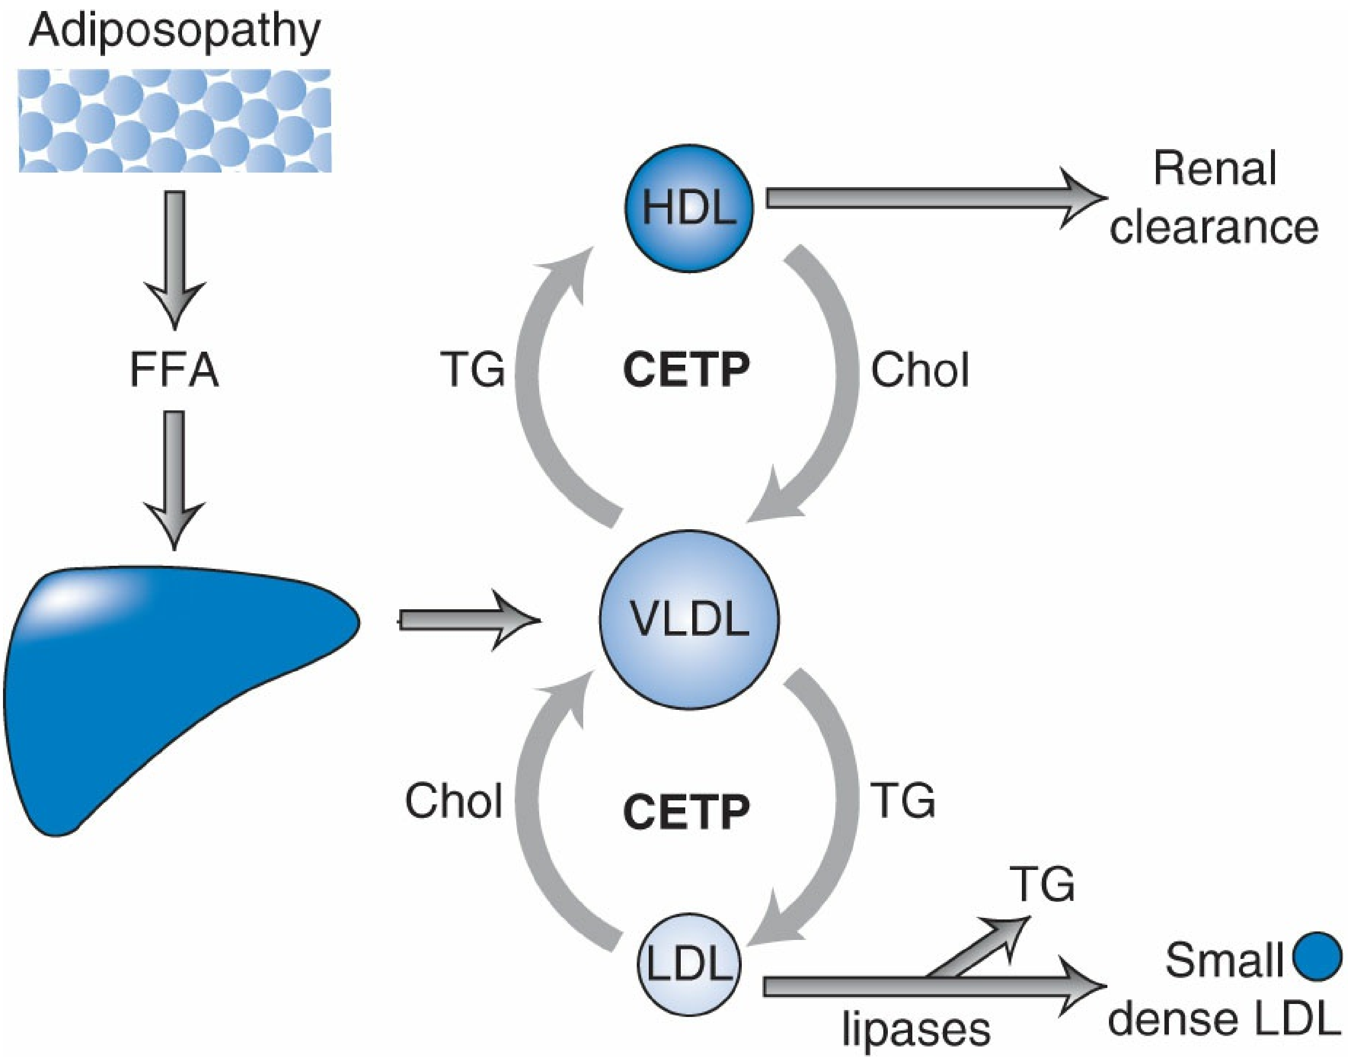

Figure 8-6 The role of CETP in creation of atherogenic dyslipidemia.[13] Role of cholesterol ester transfer protein (CETP) in the creation of an atherogenic lipid of someone with hypertriglyceridemia. Cholesterol-rich very low density lipoprotein (VLDL), low high-density lipoprotein cholesterol (HDL-C), as well as small dense low-density

lipoprotein cholesterol (LDL-C) is a pattern often observed in patients with metabolic syndrome as well as those with type 2 diabetes. With permission from Bays H, Stein EA. Pharmacotherapy for dyslipdaemia—current therapies and future agents. Expert Opin Pharmacother. 2003;4:1901–1938.

Patients with atherogenic dyslipidemia may be effectively managed with weight reduction and increased physical activity. Pharmacologic agents that enhance the removal of remnant VLDL and small dense LDL particles (i.e., statins) and that lower TG levels (i.e., Omega 3 fatty acids or fibrates) may be effective in the management of these patients.

Familial Hypercholesterolemia

FH is a disorder of defective LDL-C clearance. This autosomal dominant disorder is strongly associated with premature CHD.[24,25] Most recent estimates indicate that the prevalence of heterozygous FH (HeFH) ranges from 1 of 250 to 1 of 500 people in the United States.[26] Homozygous FH (HoFH) may occur in 1 of 1 million to 1 of 250,000 people in the United States. The most common cause of this disorder is a genetic mutation resulting in a defective or absent LDL receptor. Consequently, heterozygotes possess approximately half the number of functioning LDL receptors and double the LDL-C level of unaffected patients (LDL-C levels ranging between 250 and 450 mg/dL). Clinically, FH patients may exhibit excess cholesterol deposition in the iris, clinically manifested as arcus senilis. Cholesterol may also deposit in tendons, particularly the Achilles' tendon and extensor tendons of the hands, resulting in tendon xanthomas. The clinical diagnosis of FH is established by documenting a very high LDL-C level, a strong family history

---

of hypercholesterolemia and premature CHD events, and the presence of tendon xanthomas. Untreated HeFH patients have approximately a 5% chance of a myocardial infarction (MI) by age 30, a 50% chance by age 50, and an 85% chance by age 60. The mean age of death in untreated male heterozygotes is in the mid-50s; for untreated female heterozygotes, it is in the mid-60s.[25]

Homozygotes generally have LDL-C levels greater than 500 mg/dL. This rare disorder results in CHD by age 10 to 20 years. Because these individuals have lost the ability to clear cholesterol-carrying lipoproteins from the circulation, combination pharmacotherapy and/or LDL-apheresis may be required to help remove atherogenic particles.

Familial Defective Apo B-100

Familial defective apo B-100 (FDB) is a genetic disorder clinically indistinguishable from HeFH. These patients have normally functioning LDL receptors, but defective apolipoprotein B-100, resulting in reduced binding of LDL particles to the LDL receptor and reduced clearance of LDL particles from the systemic circulation.[27–29] As with FH, LDL-C levels are usually 250 to 450 mg/dL. Presumably, the apo E and half of the apo B in heterozygous FDB patients function normally, providing mechanisms for removal of some lipoproteins from the systemic circulation. Clinical diagnosis of FDB is based on a very high LDL-C level, a family history of premature CHD, and tendon xanthomas. The definitive diagnosis requires molecular screening techniques.

Proprotein Convertase Subtilisin/Kexin Type 9 Gain-of-Function Gene Mutation

FH may also be caused by “gain-of-function” mutations in the gene encoding for proprotein convertase subtilisin/kexin type 9 (PCSK9), an enzyme that plays an important role in cholesterol homeostasis.[30] The frequency of these mutations in patients with FH is uncertain. When PCSK9 is secreted into the plasma, it binds to the epidermal growth factor-like repeat A (EGF-A) domain of the cell-surface LDL receptors. PCSK9 binding leads to endocytosis of the LDL–LDL receptor–PCSK9 complex into intracellular lysozymes for degradation, resulting in a reduced number of LDL receptors and increased LDL-C (to approximately 300 mg/dL). Drugs that inhibit PCSK9 have demonstrated significant reductions in LDL-C in patients with HeFH, HoFH, and polygenic hypercholesterolemia.[31]

Familial Combined Hyperlipidemia

Familial combined hyperlipidemia (FCHL) is caused by increased production of apo B-containing particles, VLDL, and LDL.[32] Patients with FCHL have an elevated apo B-100 level, hypercholesterolemia with LDL-C usually in the range of 250 to 350 mg/dL, elevated TGs (usually between 200 and 800 mg/dL), and reduced levels of HDL-C. First-degree relatives of these individuals frequently have a lipid disorder and often there is a family history of ASCVD. Patients with FCHL commonly are overweight, are hypertensive, and may have metabolic disturbances such as insulin resistance, diabetes, or hyperuricemia. The diagnosis of FCHL is presumed in patients who have increased cholesterol or TG levels, a strong family history of premature CHD, and a family history of dyslipidemia.

Familial Dysbetalipoproteinemia

Familial dysbetalipoproteinemia, also called type III hyperlipidemia or remnant disease, is caused by poor clearance of VLDL and chylomicron particles from the systemic circulation as a result of a defect in apo E.[33,34] Apo E is necessary for the normal clearance of chylomicrons and VLDL. It is inherited as an E2, E3, or E4 isoform from each parent. The E2 isoform has a low binding affinity for the LDL receptor. Thus, individuals with an apo E2/E2 phenotype have delayed clearance of VLDL remnant (and possibly chylomicron) particles from the circulation and a reduced conversion of IDL to LDL particles. However, a clinically significant lipid disorder usually does not result unless triggered by other metabolic problems such as diabetes, hypothyroidism, or obesity. Patients with this disorder have high cholesterol due to enrichment of cholesterol esters in VLDL remnant particles, high TGs in the range of 400 to 800 mg/dL, and a VLDL-C to TG ratio greater than 0.3. Patients may have palmar xanthomas (yellow-orange discoloration in the creases of the palms and fingers) and tuberoeruptive xanthomas (small, raised lesions in areas of pressure, particularly the elbows and knees). A personal and family history of premature atherosclerotic vascular disease often is present. As noted above, these patients often have diabetes mellitus, hypertension, obesity, and hyperuricemia.

Familial Disorders of Triglyceride Metabolism

Familial hypertriglyceridemia (FHTG) is associated with an increase in both TG-rich VLDL particles and chylomicrons. LDL-C is generally not significantly elevated (<130 mg/dL) and HDL-C is decreased (<40 mg/dL). FHTG is usually relatively mild and asymptomatic unless secondary causes of hypertriglyceridemia are present (poorly controlled diabetes, obesity, medications, etc.). TG levels are in the range of 200 to 500 mg/dL, but may be greater than 1,000 mg/dL. Patients with more marked TG elevations (>500 mg/dL) may present with eruptive xanthomas and/or acute pancreatitis.

Rare mutations in the LPL or cofactor apo CII genes may also be associated with severe hypertriglyceridemia.[35] Familial LPL deficiency usually presents in childhood with TG levels from 2,000 to 25,000 mg/dL and lipemic plasma, pancreatitis, eruptive xanthomas, and lipemia retinalis (creamy-white appearance of retinal blood vessels). The clinical presentation of familial deficiency in apo CII is similar to familial LPL deficiency in homozygotes, but heterozygous individuals may have normal plasma lipid concentrations. Patients with familial hepatic lipase deficiency may also present with severe hypertriglyceridemia (>500–1,000 mg/dL) associated with modest elevations in LDL-C and normal to increased HDL-C. This disorder is most common in individuals of Indian ancestry.

Hypoalphalipoproteinemia

Isolated low HDL-C (<40 mg/dL) without an increase in TG level is fairly uncommon, but is associated with increased ASCVD risk. The precise molecular defects causing this problem are uncertain, although genetic influences are likely involved.[36] Tangier disease, which is characterized by low HDL-C, orange tonsils, and hepatosplenomegaly, has been linked to a defect in the ABCA-1 transporter responsible for the efflux of cholesterol from peripheral cells (i.e., inflammatory cells in the arterial wall). The inherited tendency to have low HDL-C is accentuated by lifestyle factors such as obesity, smoking, and lack of exercise. Despite strong epidemiologic evidence showing an inverse relationship between HDL-C and CHD, clinical trials demonstrating a benefit of raising isolated low HDL-C with drugs are lacking. Therapy in patients with low HDL-C is, therefore, directed at lowering LDL-C to reduce ASCVD risk. Therapies to raise HDL-C by novel mechanisms are under investigation to determine if HDL-directed strategies can reduce CHD risk.[37]

LIPOPROTEINS AND ASCVD RISK

Epidemiologic studies have conclusively established a direct relationship between blood cholesterol concentrations in a population and the incidence of ASCVD events.[38–40] For every 1% increase in blood cholesterol levels, there is a 1% to 2% increase in the risk of CHD. In addition, using gene variants that exclusively affect a biomarker of interest (i.e., that do not have pleiotropic effects on other factors), investigators have confirmed LDL-C as a causal risk factor for CAD. HDL-C is inversely associated with CHD risk. For every 1% decrease in HDL-C levels, there is a 1% to 2% increase in the risk of CHD events.[41] However, gene variants that affect HDL-C have cast doubt on whether HDL-C directly influences risk for CAD.

The role of TGs in the pathogenesis of ASCVD continues to be a subject of important investigation.[23] Most epidemiologic studies have found that a high TG level is an independent risk factor for CHD when evaluated with univariate analysis. When other lipid abnormalities such as increased LDL-C or low HDL-C are included in a multivariate analysis, TGs may lose independent predictive power. This is, in part, because it is difficult to establish a causal relationship in observational epidemiology, especially given the correlations among TGs, LDL-C, and HDL-C. Patients with hypertriglyceridemia usually have low HDL-C (due to the action of CETP and increased renal clearance of apo AI) which is an important predictor of ASCVD risk. In addition, elevated TG levels are associated with increased levels of TG-rich lipoprotein remnants (remnant VLDL and chylomicron particles and IDL), increased LDL particle concentration, and small, dense LDL particles. These particles are all potentially atherogenic and mediate a higher CHD risk than that associated with an elevated LDL-C alone.[42–45] Recent meta-analyses of epidemiologic studies found that TGs independently predicted CHD risk, even after adjustment for other lipid-risk factors.[23] High TG levels are also found in certain familial disorders, including dysbetalipoproteinemia and FCHL, which carry increased CHD risk.[33,34] Additionally, hypertriglyceridemia is associated with a procoagulant state, which promotes coronary thrombosis.[45]

A recent analysis of 185 common genetic variants mapped for plasma lipids examined the role of TGs in risk for CAD. In a model accounting for effects on LDL-C and/or HDL-C levels, the strength of a polymorphism's effect on triglyceride levels was correlated with the magnitude of its effect on CAD risk.[46] These results suggest that triglyceride-rich lipoproteins causally influence risk for CAD.

Paradoxically, very high TG levels (>500 mg/dL) are not commonly associated with an increased CHD risk, but do cause an increased risk of pancreatitis, especially when levels exceed 1,000 mg/dL. Often, a genetic defect in LPL is present in these cases that impairs the removal of TGs from TG-rich particles (VLDL and chylomicrons). These particles do not become enriched with cholesterol and, therefore, are not often atherogenic.[47] If the blood sample is stored in the refrigerator overnight, a thick creamy layer often appears on the surface, indicating the presence of chylomicrons. Although most patients with very high TGs remain free of CHD throughout their lives, some do experience ASCVD events.

Pathogenesis of Atherosclerosis

Circulating cholesterol plays a central etiologic role in the pathogenesis of atherosclerosis.[1] Atherosclerotic vascular lesions begin in the first decade of life and may progress in the presence of elevated levels of cholesterol and other uncontrolled ASCVD risk factors.[48] Atherosclerosis is considered to be a chronic inflammatory process in response to injury of the vascular endothelium by factors such as glycoxidation products in diabetes, shear stress, excess free fatty acids released by adipocytes, bacterial products, and neurohormonal abnormalities, among other factors. The damaged endothelium becomes prothrombotic, has reduced release of nitric oxide and impaired vasodilatory capacity, and releases chemoattractants for inflammatory cells and platelets. Regulation of blood cholesterol levels and management of other risk factors can restore endothelial function, nitric oxide release, and the vasodilatory response.

In patients with excess apo-B-containing lipoproteins [VLDL remnants, IDL, LDL, and Lp(a)], atherogenic particles migrate through the endothelial junction into the subendothelial space or intima. The subsequent accumulation and retention of lipoproteins in the subendothelium (Fig. 8-7)[48] is the result of binding to subendothelial matrix molecules such as chondroitin sulfate proteoglycans.

Soon after taking up residence in the subendothelial space, lipoproteins are structurally modified primarily by oxidation. Modified lipoproteins stimulate dysfunctional endothelial cells to release cell adhesion molecules (intracellular adhesion molecule 1, vascular cell adhesion molecule 1, and E-selectin) and chemoattractants (monocyte chemotactic factor 1 and macrophage colony-stimulating factor) which promote adhesion and stimulate transmigration of monocytes and lymphocytes into the intimal space.[49–51] Thus, atherosclerosis is an inflammatory process in response to retained and modified lipoproteins. Once recruited, monocytes are converted to macrophages, which ingest oxidized lipoprotein particles via special scavenger or acetyl-LDL receptors on the surface of macrophage cells.[52] Further engorgement with oxidized lipoproteins inhibits mobility of resident macrophages and the cells become cytotoxic causing further damage to the vascular endothelium. As the uptake of modified lipoproteins into macrophage cells continues, the cells become laden with lipid and eventually become foam cells (Fig. 8-8). Monocytes and foam cells continue to secrete growth factors and cytokines establishing a chronic inflammatory process and progression to a more complex atherosclerotic plaque.

During plaque growth, smooth muscle cells from the media migrate upward and proliferate near the luminal surface.[53] Collagen synthesis is also increased. This leads to conversion of early atherosclerotic lesions that are lipid rich with a thin fibrous cap to a potentially more stable lesion that has a small inner lipid core and more collagen and matrix proteins. At any given time, atherosclerotic lesions at various stages of development can be found all along the vascular arterial tree in high-risk patients (Fig. 8-7).

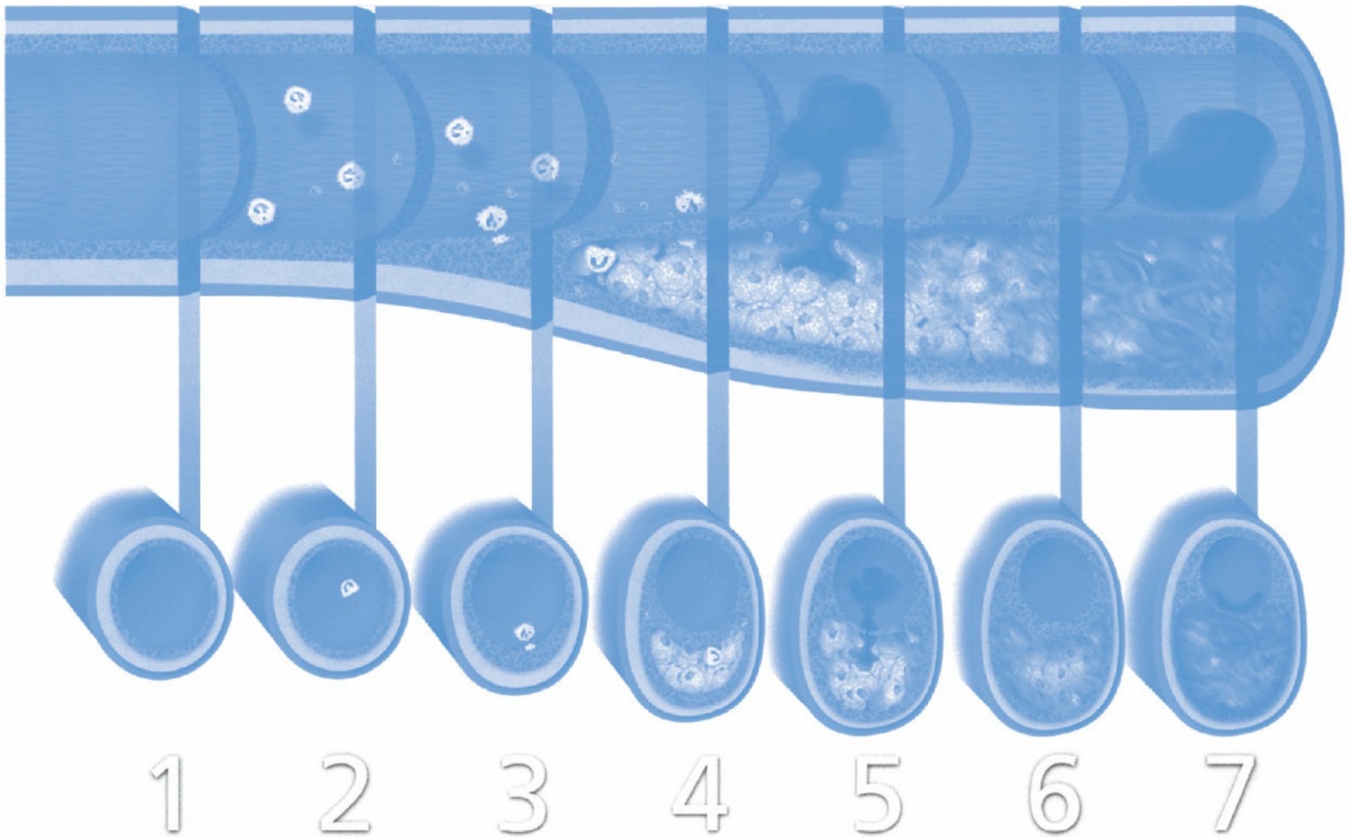

Figure 8-8 Initiation, progression, and complication of human coronary atherosclerotic plaque (numbers indicate order of progression).

As atherosclerotic lesions grow, the coronary artery remodels to accommodate the lipid-rich core. Lesions initially enlarge away from the lumen toward the media/adventitia, thus preserving the vascular lumen and ensuring normal blood flow (positive remodeling). Late in the growth of the lesion, however, the luminal space is invaded and becomes progressively narrowed as the atherosclerotic lesion progresses (negative remodeling). Inflammatory cells secrete matrix metalloproteinases that degrade collagen and fibrin produced by arterial smooth muscle cells, causing a weakened fibrous cap and a lesion more vulnerable to plaque rupture.[54] Apoptosis (cell death) of smooth muscle cells in the shoulders of the atherosclerotic cap further weakens the lesion.[55] These processes increase the chance that the atherosclerotic lesion may rupture or erode, especially at the shoulders of the lesion, and expose the underlying tissue to circulating blood elements.[56] Collagen in the exposed plaque can trigger platelet activation, and tissue factor produced by macrophages and smooth muscle cells activates the coagulation cascade. Platelets may adhere and microthrombi may form. The resultant clot can occlude blood flow entirely, causing MI. More commonly, only partial occlusion of blood flow occurs, causing transient ischemic symptoms or unstable angina. The clot creates a barrier between the underlying tissue and circulating blood and allows healing of the plaque rupture. This process of fissuring and re-healing appears to lead to the more complicated lesions of atherosclerosis.

Atherosclerotic lesions exist along a continuum from vulnerable lipid-rich lesions that are prone to rupture and cause a thrombosis to more stable lipid-poor, fibrin-

and collagen-rich lesions. Younger atherosclerotic lesions occupy only the intimal space, whereas the older lesions may protrude into the luminal space. In fact, the culprit lesion that results in acute MI is usually not at the site of the greatest stenosis, but distal to it.[55]

CLINICAL EVALUATION AND MANAGEMENT OF ASCVD RISK

Assessment of the Standard Lipid Panel and the Role of Advanced Lipid Testing

The routine lipid panel includes standardized measurements of total cholesterol (TC), HDL-C, and TGs. Although it is possible to measure LDL-C directly, it is common for most laboratories to calculate LDL-C. TC, HDL-C, and TGs are measured directly and then the Friedewald equation is applied to calculate LDL-C:

$$\text{LDL-C} = \text{total cholesterol} - (\text{HDL-C} + \text{VLDL-C}) \qquad \text{(Eq. 8-1)}$$

Because the ratio of cholesterol to TGs in VLDL is 1:5, VLDL-C is estimated by dividing the total TG level by 5. Thus, the formula is rewritten as

$$\text{LDL-C} = \text{total cholesterol} - (\text{HDL-C} + \text{TG}/5) \qquad \text{(Eq. 8-2)}$$

If the TG level is greater than 400 mg/dL the formula for estimating VLDL-C is not accurate and, therefore, LDL-C cannot be calculated. An accurate LDL-C calculation by the Friedewald equation also requires that the patient fast for 10 to 12 hours which provides sufficient time for exogenous TGs, carried by chylomicrons, to be cleared from the systemic circulation. Most laboratories can measure LDL-C directly but this is necessary only when the TG level is greater than 400 mg/dL or the patient has not fasted.

In the presence of cardiometabolic disturbances including the metabolic syndrome, insulin resistance, impaired glucose tolerance, diabetes, hypertriglyceridemia, as well as chronic kidney disease (CKD), the calculated or direct measurement of LDL-C may not provide a complete assessment of the lipid-related cardiovascular risk. Cardiometabolic disorders are often associated with the atherogenic dyslipidemia described above, in which there are near-normal to modest elevations of LDL-C, reduced HDL-C levels, elevations of TGs, and an excess of atherogenic small, dense LDL particles. When LDL-C levels are near-normal to modestly elevated and the LDL particle concentration (LDL-P) is elevated, the measures are considered to be “discordant.”

There are a number of advanced lipid/lipoprotein tests to determine the concentration and/or the relative size distribution of both LDL and HDL particles. These include gradient gel electrophoresis, vertical automated profile, nuclear magnetic resonance spectroscopy, and ion mobility analysis. Data from both the Framingham Offspring Study and the Multi-Ethnic Study of Atherosclerosis demonstrated that patients with discordantly high LDL-P compared to LDL-C had higher CVD event rates, while patients with discordantly low LDL-P compared to LDL-C had lower CVD event rates.[57,58] CVD risk, therefore, tracked most closely with levels of LDL-P. Apo B is another measure of concentrations of atherogenic lipoproteins, including remnant VLDL particles and LDL particles and is strongly related to CVD risk.[59]

Non–HDL-C provides a simple and easily calculated estimate of the excess CVD risk associated with the atherogenic dyslipidemia.[7]

It is a single measurement of cholesterol carried by all potentially atherogenic particles, including VLDL, VLDL remnants, IDL, and LDL particles and can give the clinician information regarding the patient’s CVD risk when LDL-C cannot reliably be calculated or in the presence of excess VLDL-C and excess LDL particle concentration. Non–HDL-C is calculated by the following formula:

$$\text{Non–HDL-C} = \text{total cholesterol} - \text{HDL-C} \qquad \text{(Eq. 8-3)}$$

As mentioned previously, non–HDL-C can be calculated in both the fasting and non-fasting state because VLDL-C does not need to be estimated.

There are a number of guidelines for the management of lipid-related ASCVD risk and there is considerable variation in the recommended targets and goals of therapy, including LDL-C, non–HDL-C, LDL-P, and apo B. A recent review of guidelines from major US and international professional societies compares recommendations for lipid/lipoprotein targets and initiation of lipid-lowering therapies.[8]

Guidelines for the Management of Dyslipidemia to Reduce ASCVD Risk

In 2013 the ACC and the AHA published updated guidelines for management of blood cholesterol to reduce ASCVD risk.[5] Previous guidelines have focused on the fasting lipid panel as the initial evaluation of lipid-related risk. Within each category of ASCVD risk, lipid goals were then specified to achieve optimal risk reduction. In 2013 experts determined that current clinical trial data do not support the previous approach and that data are inadequate to indicate specific lipoprotein targets or goals of therapy. Therefore, the panel made no recommendation for or against specific targets (LDL-C or non–HDL-C) for primary or secondary ASCVD prevention. Instead, four groups of patients were identified in which there is the most extensive evidence of the benefit of statin therapy for prevention of ASCVD:

1. Individuals with clinical ASCVD,
2. Individuals with primary elevations of LDL-C ≥190 mg/dL,
3. Individuals 40 to 75 years of age with diabetes and LDL-C 70 to 189 mg/dL, and
4. Individuals without clinical ASCVD or diabetes who are 40 to 75 years of age with LDL-C 70 to 189 mg/dL and an estimated 10-year ASCVD risk of ≥7.5%.

For each risk group the guidelines recommend an intensity of statin therapy, either moderate or high intensity (Table 8-3). Low-intensity statins are recommended only in patients who have experienced or are at risk for adverse effects of treatment. The guidelines do not support dose titration to achieve specific levels of LDL-C, non–HDL-C, or apo B, as recommended in previous guidelines (Fig. 8-9). Measurement of the lipid panel is recommended at 4 to 12 weeks after initiation of statin therapy to assess compliance with lifestyle recommendations and medication, as well as response to therapy. Regular monitoring of the lipid panel is then recommended every 3 to 12 months as clinically indicated.

For primary prevention of ASCVD the recommended risk assessment tool is the new CV Risk Calculator based on the Pooled Cohort Equations as described in the 2013 ACC/AHA Guideline on the Assessment of Cardiovascular Risk.[6] The equations are derived from large, diverse, community-based cohorts that are generally representative of the US population of whites and African Americans. The calculator provides race- and sex-specific estimates of the 10-year risk of first hard ASCVD event (nonfatal MI, CHD death, fatal or nonfatal stroke) and should be used in non-Hispanic African American and non-Hispanic whites between 40 and 79 years of age. Lifetime- or 30-year risk is also provided for individuals aged 20 to 59 years who are not at high short-term risk. Variables considered in the risk calculation include age, sex, race, total cholesterol, HDL-C, systolic blood pressure, treatment for hypertension, tobacco use, and diabetes. To further refine risk assessment, optional factors that may be considered include family history of premature ASCVD, hs-CRP, LDL-C ≥160 mg/dL, coronary artery calcium scoring, and ankle brachial index. The National Lipid Association Patient-Centered Recommendations: Part 2 provide recommendations for risk assessment in non-Hispanic whites and other racial and ethnic groups which were not a part of populations used to derive the ACC/AHA Pooled Cohort Equations.[60]

Table 8-3

Intensity of the Various Statins[5]

High intensity (when taken as prescribed will reduce LDL-C by ≥50%	Atorvastatin (40 mg)* – 80 mg Rosuvastatin 20 (40) mg
Moderate intensity (when taken as prescribed will reduce LDL-C by 30% < 50%)	**Atorvastatin 10** (20) **mg** **Rosuvastatin** (5) **10 mg** **Simvastatin 20–40 mg**

	Pravastatin 40 (80) **mg** **Lovastatin 40 mg** Fluvastatin XL 80 mg **Fluvastatin 40 mg bid** **Pitavastatin 2–4 mg**
Low intensity (when taken as prescribed will reduce LDL-C by <30% on average	Simvastatin 10 mg **Pravastatin 10–20 mg** **Lovastatin 20 mg** Fluvastatin 20–40 mg Pitavastatin 1 mg

The doses listed in parenthesis were not evaluated in randomized controlled trials.

*Evidence is from one randomized controlled trial Bold—Doses of statins that were evaluated in randomized controlled trials

Patients with a 10-year risk of ≥7.5% should be engaged in a patient–clinician discussion of the ASCVD risk reduction benefits of statin therapy, potential adverse drug effects, potential drug–drug interactions, and consideration of patient preferences to determine if statin therapy is appropriate (Fig. 8-10).

CASE 8-1

QUESTION 1: B.C. is a 46-year-old peri-menopausal white female who has recently relocated to the area and is establishing care with a gynecologist. As part of her annual evaluation a routine lipid panel is obtained. She takes no prescription medications but does take a number of dietary supplements and vitamins, including krill oil, multivitamin, B-complex, and vitamin D. She has no history of tobacco use, hypertension, or diabetes. She states she was told a number of years ago that her LDL “bad” cholesterol was elevated, but her HDL “good” cholesterol was high and no treatment was indicated. She has enjoyed jogging and spin classes but says that as she gets older she is more fatigued and sore with exercise. She follows a Mediterranean style diet and has a glass of red wine daily.

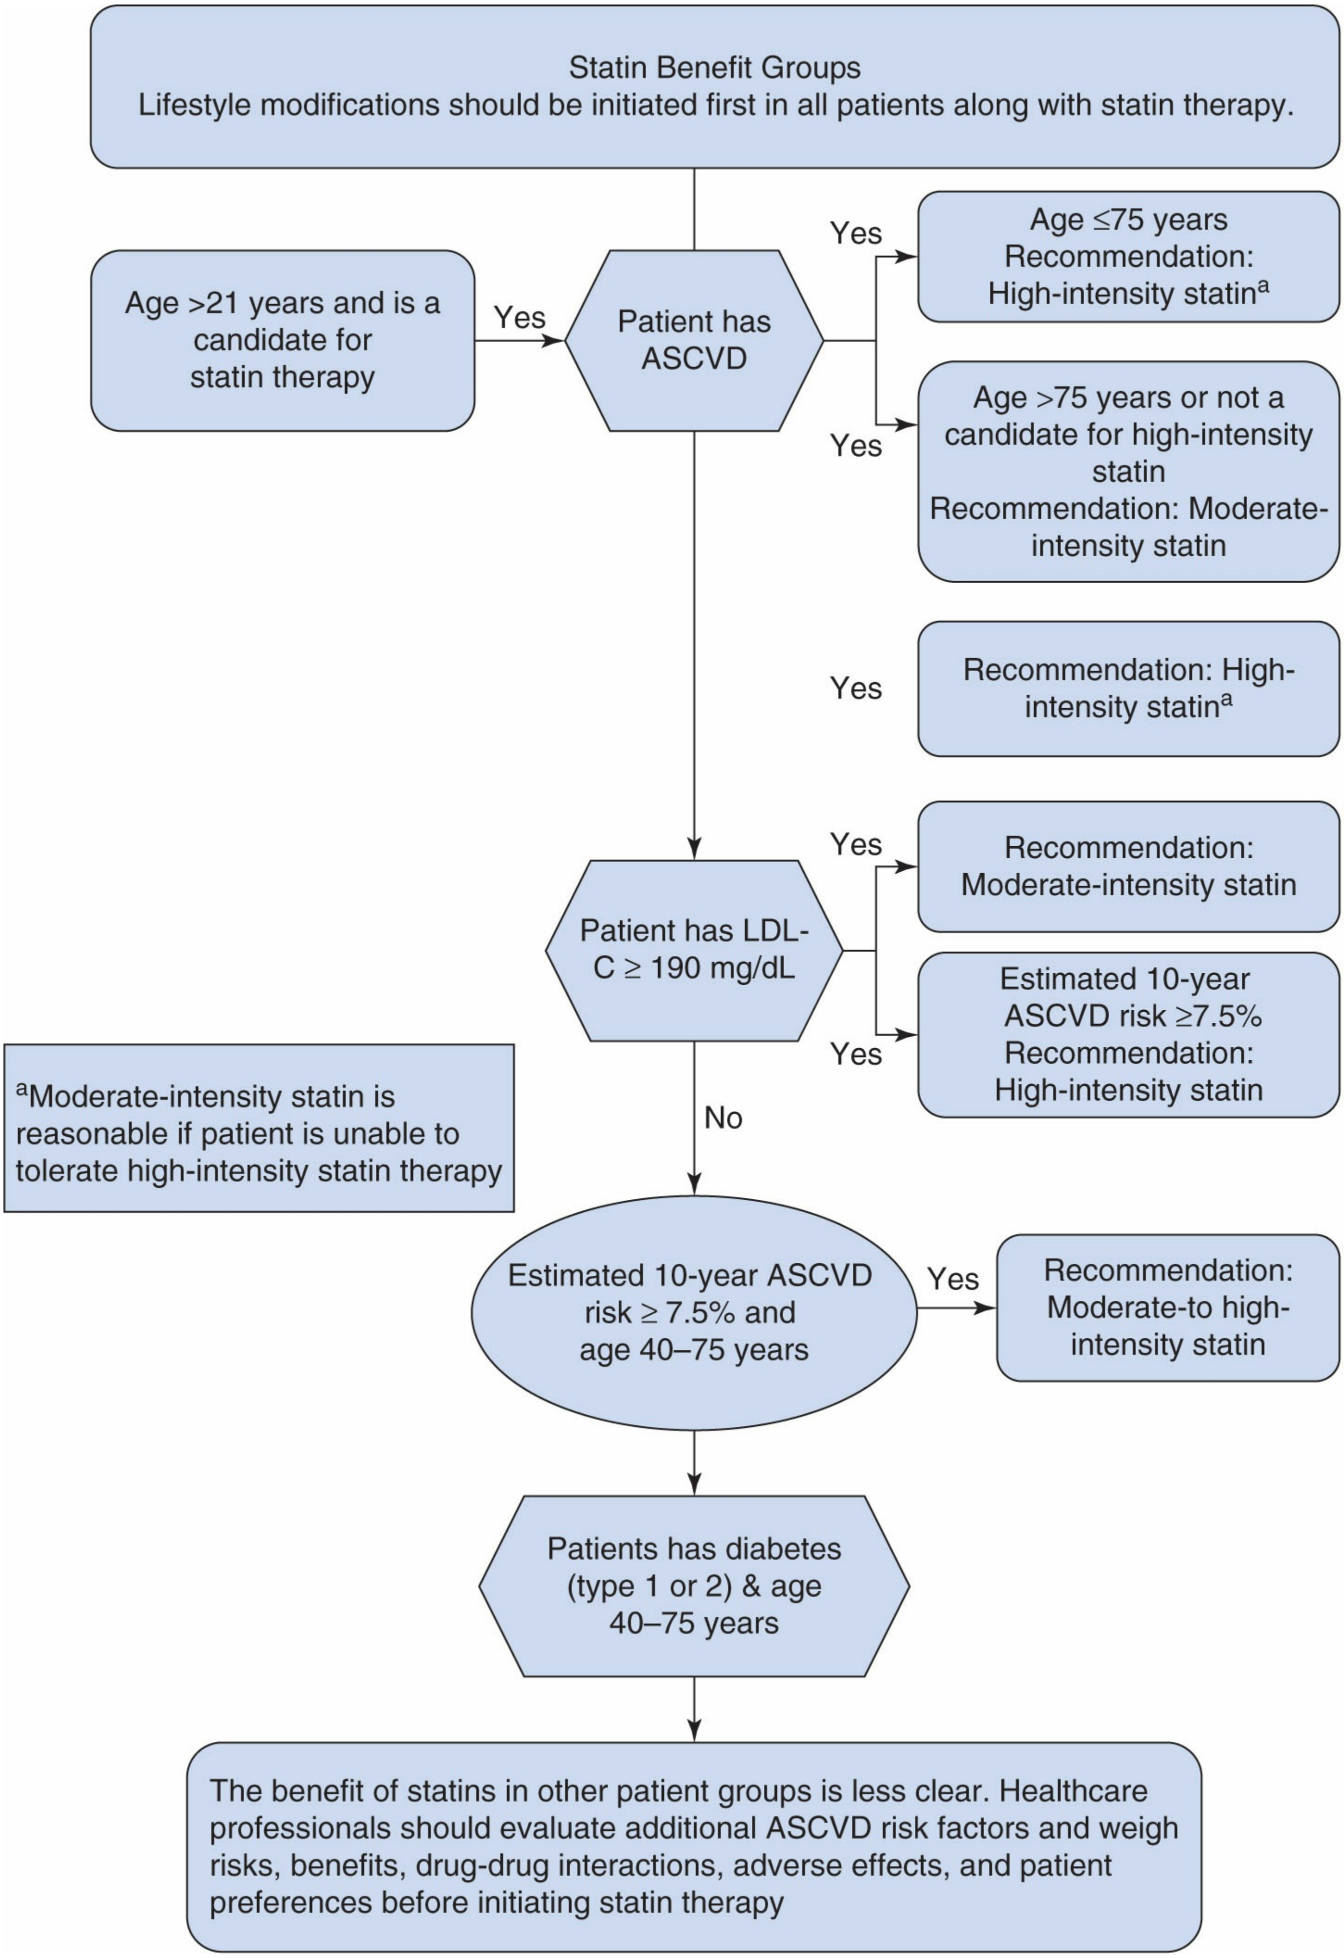
Her father is alive at age 72 and takes statin therapy for hyperlipidemia, though she is uncertain of the severity of his lipid disorder. He has no history of cardiovascular disease. Her mother is a 71-year-old diabetic and underwent coronary stent placement last year following the onset of angina and an abnormal stress test. She was started on statin therapy at the time of her procedure. Her brother is overweight, has hypertension and borderline diabetes, and is also on statin therapy and fenofibrate.

On physical exam the patient has the following: normotensive (128/76 mm Hg); carotid pulses with normal amplitude and no bruits; 2/6 crescendo/decrescendo noted at the left sternal border; no abdominal bruit; peripheral pulses 2+; no tendon xanthomas, corneal arcus, or xanthelasmas.

Following a 12-hour fast the patient’s lipid panel shows the following results:

Total cholesterol, 290 mg/dL
HDL-C, 56 mg/dL
LDL-C calculated, 218 mg/dL
TG, 132 mg/dL

What is your assessment of B.C.’s lipid panel results?



Statin Benefit Groups
Lifestyle modifications should be initiated first in all patients along with statin therapy.
Age >21 years and is a candidate for statin therapy
Yes
Patient has ASCVD
Yes
Age ≤75 years Recommendation: High-intensity statin[a]
Yes
Age >75 years or not a candidate for high-intensity statin Recommendation: Moderate-intensity statin
Yes
Recommendation: High-intensity statin[a]
Yes
Recommendation: Moderate-intensity statin
Patient has LDL-C ≥ 190 mg/dL
Yes
Estimated 10-year ASCVD risk ≥7.5% Recommendation: High-intensity statin
No
[a]Moderate-intensity statin is reasonable if patient is unable to tolerate high-intensity statin therapy
Estimated 10-year ASCVD risk ≥ 7.5% and age 40–75 years
Yes
Recommendation: Moderate-to high-intensity statin
Patients has diabetes (type 1 or 2) & age 40–75 years
The benefit of statins in other patient groups is less clear. Healthcare professionals should evaluate additional ASCVD risk factors and weigh risks, benefits, drug-drug interactions, adverse effects, and patient preferences before initiating statin therapy

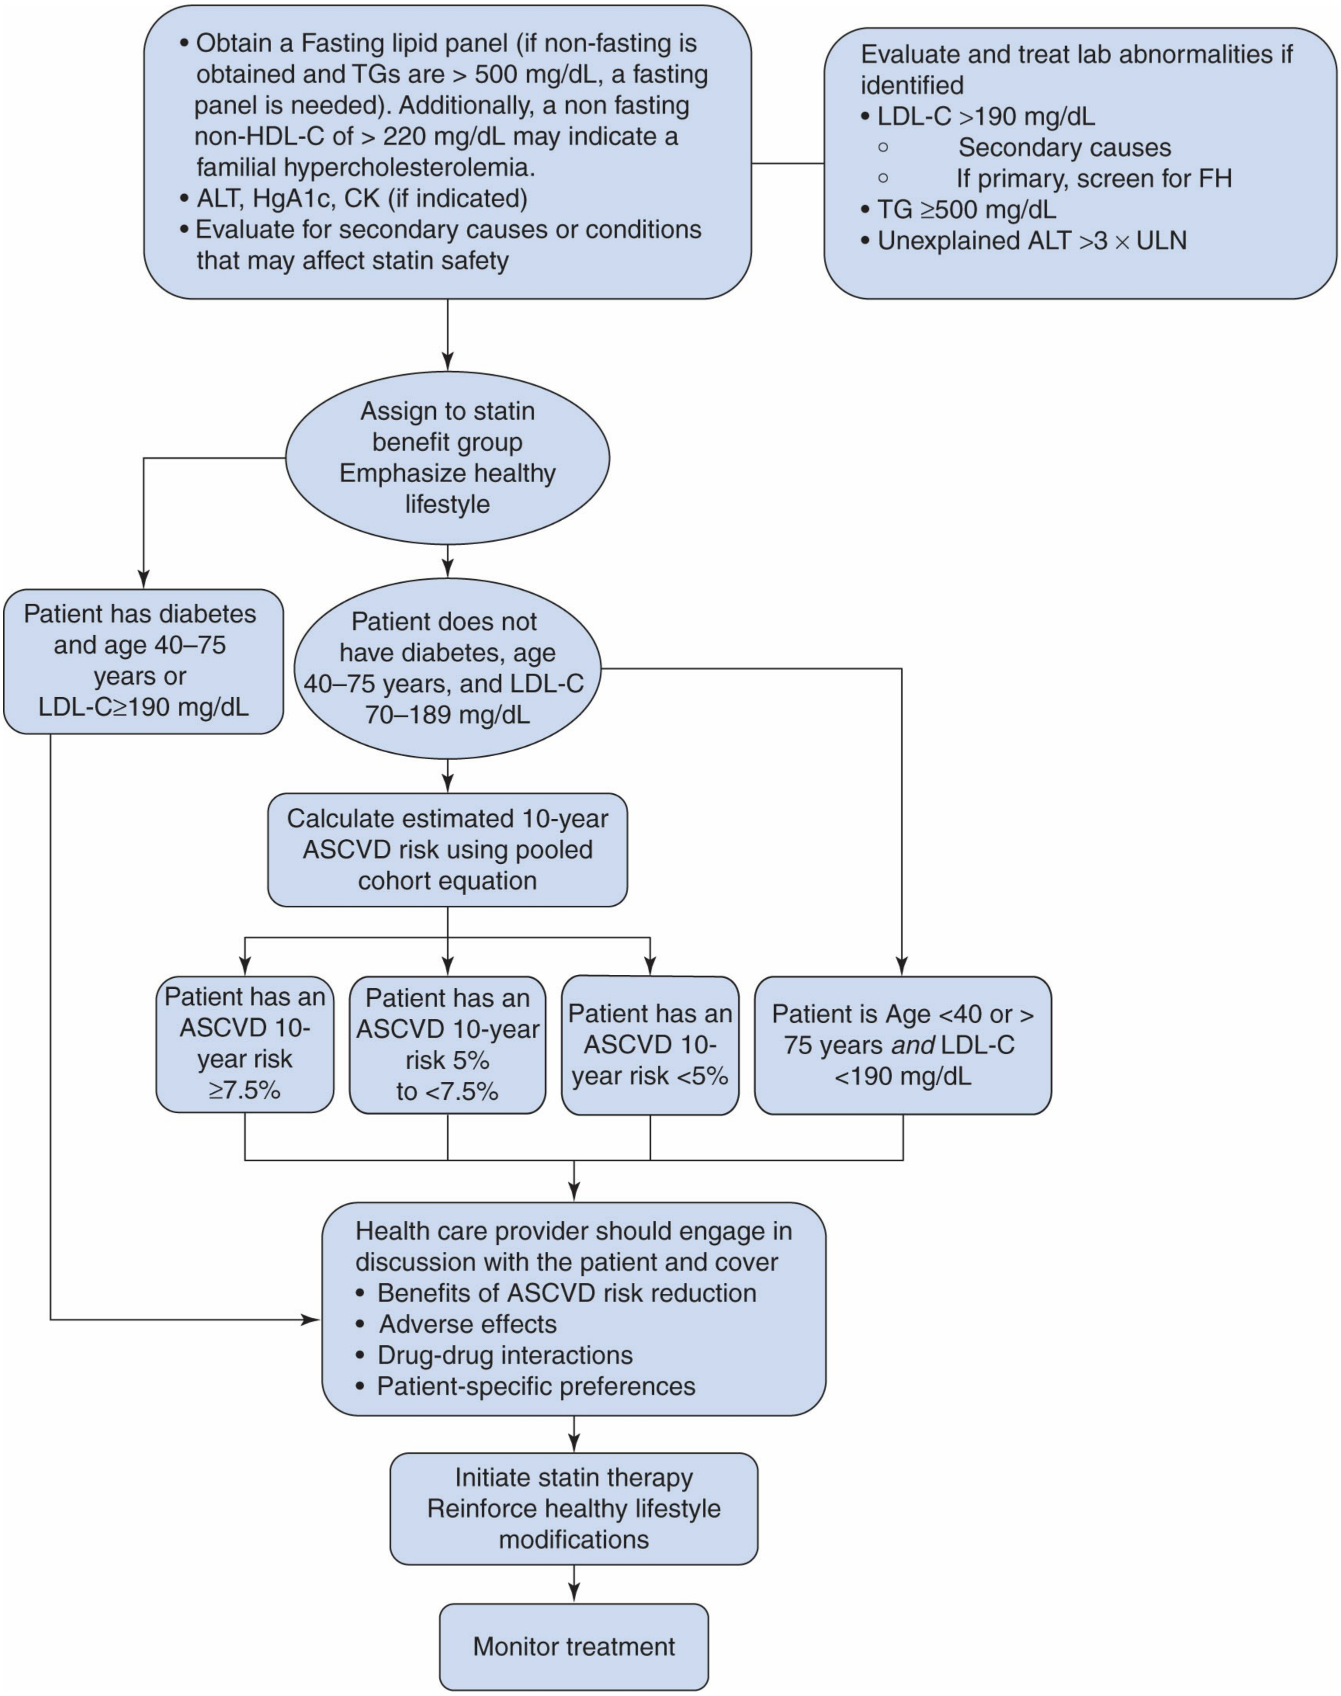
Figure 8-9 Recommendations for the intensity of statin therapy based on statin benefit group diagram. (Adapted

from Stone NJ et al. 2013 ACC/AHA guideline on the treatment of blood cholesterol to reduce atherosclerotic cardiovascular risk in adults: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol. 2014;63:2889–2934. doi:10.1016/j.jacc.2013.11.002.)

The NLA Recommendations for Patient-Centered Management of Dyslipidemia were published in 2014. Similar to NCEP ATP III Guidelines, these comprehensive recommendations for management of a variety of dyslipidemias continue to recommend lipoprotein targets (non–HDL-C and LDL-C) and titration to achieve goals of therapy (Table 8-4).[7]

The patient's LDL-C is very high and she would qualify for statin therapy as defined by both the ACC/AHA and NLA recommendations for management of hypercholesterolemia. Her HDL-C is near the average range for a woman and her TG level is considered normal (<150 mg/dL). There has been a misconception among some providers and patients that a normal or high HDL-C level is "protective" in the presence of hypercholesterolemia, based on a TC/HDL-C ratio of <3.5, and that statin therapy is not indicated. However, in the presence of very high elevations of LDL-C levels all current and previous guidelines recommend statin therapy regardless of baseline HDL-C.

In the presence of very high LDL-C levels it is important to consider a number of issues prior to initiation of therapy. The patient's lifestyle, including diet and exercise, may play an important role in B.C.'s new diagnosis of dyslipidemia. However, she is actually quite compliant with lifestyle recommendations for optimal cardiovascular health and this is unlikely to be a factor in her lipid levels. Careful review of family history of hypercholesterolemia and ASCVD by construction of a detailed pedigree can identify patients with possible HeFH or HoFH. B.C.'s father has dyslipidemia of uncertain severity and is on statin therapy, but he has no history of premature ASCVD. Her mother developed ASCVD after age 65 and a long history of diabetes. Statin therapy was not prescribed until her stent placement and FH is unlikely. Her brother has a mixed dyslipidemia, most likely exacerbated by overweight and poorly controlled diabetes. Thus, based on this brief pedigree the diagnosis of FH is unlikely. Classic physical examination findings of tendon xanthomas, corneal arcus before age 45, and xanthelasmas are often, but not always present in FH. B.C. does not have these findings. The patient does have a systolic murmur on cardiac examination which may be indicative of aortic valvular disease, a very common problem in patients with HoFH.



• Obtain a Fasting lipid panel (if non-fasting is obtained and TGs are > 500 mg/dL, a fasting panel is needed). Additionally, a non fasting non-HDL-C of > 220 mg/dL may indicate a familial hypercholesterolemia.
• ALT, HgA1c, CK (if indicated)
• Evaluate for secondary causes or conditions that may affect statin safety
Evaluate and treat lab abnormalities if identified
• LDL-C >190 mg/dL
○ Secondary causes
○ If primary, screen for FH
• TG ≥500 mg/dL
• Unexplained ALT >3 × ULN
Assign to statin benefit group Emphasize healthy lifestyle
Patient has diabetes and age 40–75 years or LDL-C≥190 mg/dL
Patient does not have diabetes, age 40–75 years, and LDL-C 70–189 mg/dL
Calculate estimated 10-year ASCVD risk using pooled cohort equation
Patient has an ASCVD 10-year risk ≥7.5%
Patient has an ASCVD 10-year risk 5% to <7.5%
Patient has an ASCVD 10-year risk <5%
Patient is Age <40 or > 75 years and LDL-C <190 mg/dL
Health care provider should engage in discussion with the patient and cover
• Benefits of ASCVD risk reduction
• Adverse effects
• Drug-drug interactions
• Patient-specific preferences
Initiate statin therapy Reinforce healthy lifestyle modifications
Monitor treatment

Figure 8-10 Recommendations for initiating statin therapy in patients without clinical ASCVD.(Adapted from Stone NJ et al. 2013 ACC/AHA guideline on the treatment of blood cholesterol to reduce atherosclerotic cardiovascular risk in adults: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol. 2014;63:2889–2934. doi:10.1016/j.jacc.2013.11.002.)

Mean TC is typically lower in premenopausal women than in age-matched men. Premenopausal women have a less pro-atherogenic lipid profile with higher HDL-C levels (average 10 mg/dL) and lower LDL-C and non–HDL-C levels than age-matched men. Due to the hormonal alterations during the perimenopausal period, LDL-C levels rise and are often higher than in age-matched men. Postmenopausal women also have a higher incidence of high TG and low HDL-C levels, with an increase in small, dense LDL particles. It is not uncommon for women without a prior history of dyslipidemia to be newly diagnosed in the perimenopausal period and B.C. may be just such a patient.

Table 8-4

NLA Criteria for ASCVD Risk Assessment and Treatment Goals for Atherogenic Cholesterol, and Levels at Which Pharmacologic Therapy Should Be Considered[7]

Risk	Low	Moderate	High	Very High
Criteria	■ 0–1 Major ASCVD risk factor ■ Consider other known risk factors	■ Major ASCVD risk factors ■ Consider other risk factors ■ Consider quantitative risk scoring	■ ≥3 major ASCVD risk factors ■ Chronic kidney disease stage 3B or 4[a] ■ Quantitative risk score reaching the high-risk threshold ■ LDL-C ≥ 190 mg/dL (severe hypercholesterolemia ■ Diabetes mellitus[b] (type 1 or 2) with 0–1 major ASCVD risk factor and no evidence of end-organ damage	■ ASCVD diabetes[b] (type 1 or 2) and >2 major ASCVD risk factors or evidence of end-organ damage
Treatment Goal				
Non–HDL-C (mg/dL)	<130	<130	<130	<100
LDL-C (mg/dL)	<100	<100	<100	<70
Consider Pharmacologic Therapy				
Non–HDL-C mg/dL	≥190	≥160	≥130	≥100
LDL-C (mg/dL)	≥160	≥130	≥100	≥70

[a] Chronic kidney disease stage 3B or 4 = estimated glomerular filtration rate of 30 to 44 mL/minute and 15 to 29 mL/minute, respectively. Risk calculators should not be used in these patients as they underestimate risk.

[b] Diabetic patients plus 1 major ASCVD risk factor, treating to a non–HDL-C goal of <100 mg/dL (LDL-

C).Adapted from Jacobson TA et al. National lipid association recommendations for patient-centered management of dyslipidemia: part 1—full report. J Clin Lipidol. 2015;9:129–169.

ASCVD, atherosclerotic cardiovascular disease; LDL-C, low-density lipoprotein cholesterol; non–HDL-C, non–high-density lipoprotein cholesterol.

CASE 8-1, QUESTION 2: Is there any evidence for other potential causes of B.C.'s dyslipidemia?

As a routine every patient with dyslipidemia should be evaluated for secondary causes of elevated LDL-C, non–HDL-C, or TG. Conditions that may be associated with lipid abnormalities include diabetes, CKD and nephrotic syndrome, obstructive liver disease, hypothyroidism, anorexia nervosa, polycystic ovarian syndrome, and pregnancy, among others (Table 8-5).[5] Average values of total-C, LDL-C, HDL-C, and TG steadily rise throughout pregnancy and levels peak near full-term. In uncomplicated or "normal" pregnancies, neither total-C nor TG exceeds 250 mg/dL at any time during pregnancy. A number of drugs are associated with dyslipidemia or worsening of baseline lipid abnormalities, including exogenous estrogen and progesterone therapy, and a careful review of the patient's medication regimen is necessary prior to initiation of lipid-lowering therapy. B.C. is currently perimenopausal and does not take any medications associated with exacerbation of dyslipidemia nor any form of exogenous hormone replacement therapy or oral contraception.

Table 8-5

Classification of Secondary Causes of Dyslipidemia[5]

Cause	Increased LDL-C	Increased TG
Drugs/medications	Glucocorticoids, amiodarone, diuretics, cyclosporine	Hormone therapy, glucocorticoids, bile acid sequestrants, protease inhibitors, retinoic acid, anabolic steroids, tamoxifen, sirolimus, atypical antipsychotics (predominately olanzapine and clozapine), raloxifene, β -blockers, thiazide diuretics
Dietary Influences	Anorexia, trans fats or saturated fats, weight gain	Very low fat diets, weight gain, high carbohydrate intake (refined), and excessive alcohol use
Disease states	Nephrotic syndrome, biliary obstruction	Nephrotic syndrome, chronic renal failure, lipodystrophies
Disorders of metabolism	Obesity, pregnancy, hypothyroidism	Hypothyroidism, poorly controlled diabetes, pregnancy, and obesity

---

CASE 8-1, QUESTION 3: Further review of B.C.'s laboratory studies showed the following:

Glucose, 92 mg/dL
Alanine aminotransferase (ALT), 24 mg/dL
Aspartate aminotransferase (AST), 18 mg/dL

Creatinine, 0.9 mg/dL

Thyroid-stimulating hormone (TSH), 57 international units (IU)/mL

Laboratory evaluation has revealed that B.C.'s fatigue and muscle soreness are likely due to hypothyroidism, which has also exacerbated her previous dyslipidemia. She is placed on thyroid replacement therapy and with normalization of her thyroid function her follow-up laboratory results show the following:

TSH, 1.254 IU/mL
TC, 215 mg/dL
HDL-C, 59 mg/dL
LDL-C calculated, 132 mg/dL
TG, 118 mg/dL

What is the next step in the evaluation of B.C.'s ASCVD risk?

B.C. has no other ASCVD risk factors or risk equivalents other than mild dyslipidemia. Using the ACC/AHA Pooled Cohort Equations or CV Risk Calculator her 10-year risk of ASCVD event is 0.9%. According to both the ACC/AHA and NLA recommendations for lipid management there is currently no indication for initiation of statin therapy.

The 2015 Standards of Diabetes Care of the American Diabetes Association (ADA) were revised to recommend initiation and intensification of statin therapy (high versus moderate) in patients with diabetes based on the individual patient's risk profile.[61] However, the ADA notes that the presence of diabetes confers significant risk of ASCVD and that the ACC/AHA CV Risk Estimator is of limited use in diabetics. Recommendations are made for patients <40, 40 to 75, and >75 years of age for moderate- or high-intensity statin therapy in the presence of ASCVD risk factors or overt ASCVD (Table 8-6).

The 2013 Clinical Practice Guideline for Lipid Management in Chronic Kidney Disease (CKD), published by the Kidney Disease: Improving Global Outcomes (KDIGO) Panel, notes that in nondialysis-dependent CKD patients the relationship between LDL-C and ASCVD events is weaker than in the general population.[62] This is likely related to lipoprotein metabolic abnormalities characterized by lower levels of LDL-C, elevated LDL-P, an increase in small dense LDL, reduced HDL-C, and elevated TG. Therefore, according to KDIGO guidelines the measured LDL-C may be less useful as a marker of coronary risk among people with advanced nondialysis-dependent CKD and does not serve as an indication for pharmacologic treatment. Instead, therapy is guided by the absolute risk of coronary events based on patient age and stage of CKD or estimated glomerular filtration rate (eGFR). Specific doses of individual statins are recommended for each stage of CKD or eGFR and dose titration is not indicated. Statin therapy or combination therapy with statin and ezetimibe is not recommended in adults with dialysis-dependent CKD due to lack of evidence of ASCVD risk reduction in patients with stage V CKD. However, therapy may be continued in patients already receiving therapy at the time of initiation of dialysis (Table 8-7).

CASE 8-2

QUESTION 1: S.W. is a 51-year-old African American male with CKD due to polycystic kidney disease. He has no history of tobacco use or diabetes, but is treated for hypertension. He is very active and works in landscape maintenance, but does not have a program of consistent aerobic exercise. He follows a heart-healthy diet consistent with the DASH (Dietary Approaches to Stop Hypertension) recommendations and has maintained a normal BMI. He is referred for nephrology consultation and the following results are obtained:

eGFR, 42 mL/minute
TC, 187 mg/dL
HDL, 39 mg/dL
LDL-C calculated, 102 mg/dL
TG, 230 mg/dL
HgbA$_{1c}$, 6.8%
BP, 126/68 mm Hg

What is your assessment of S.W.'s ASCVD risk and his lipid panel results?

S.W. has stage 3b CKD defined as an eGFR between 30 and 44 mL/min/1.73 m^2. According to the NLA Recommendations for Patient-Centered Management of Dyslipidemia, patients with stage 3b to stage 4 CKD are at high risk for ASCVD and should be considered for drug therapy. Statin therapy with or without ezetimibe are recommended therapies in CKD patients who are nondialysis dependent and the goals of therapy are non–HDL-C <130 mg/dL and/or LDL-C <100 mg/dL.

Table 8-6

ADA Recommendations for Statin Treatment in People with Diabetes[61]

Age	<40 years	40–75 years	>75 years
Risk factors	Zero risk factor(s) for CHD[a] Overt CHD[b]	Zero risk factor(s) for CHD Overt CHD	Zero risk factor(s) for CHD Overt CHD
Recommended dose of statin	■ No statin if zero risk factors ■ Moderate or high intensity in presence of CHD risk factor(s) ■ High if overt CHD	■ Moderate if no risk factors ■ High intensity in presence of CHD risk factor(s) ■ High if overt CHD	■ Moderate if no risk factors ■ Moderate or high intensity in presence of CHD risk factor(s) ■ High if overt CHD
Recommended monitoring of lipid panel	Annually or as needed	As needed to assess for adherence	As needed to assess for adherence

Statin therapy should be initiated as an adjunct to lifestyle modifications.

[a] CHD risk factors include hypertension, smoking, LDL-C ≥ 100 mg/dL, being overweight, and obesity.

[b] Overt CHD includes those who have had a previous cardiovascular event or an acute coronary syndrome.

CHD, coronary heart disease.

Adapted from Cromwell et al. LDL particle number and risk of future cardiovascular disease in the Framingham Offspring Study—implications for LDL management. J Clin Lipidol. 2007;1:583–592.

Table 8-7

KDIGO Clinical Practice Guideline for Lipid Management in Chronic Kidney Disease[62]

Chronic Kidney Disease Severity	Treatment Recommendations
Age ≥ 50 years of age with eGFR <60 mL/minute/1.73 m^2 not on HD or have a history of kidney transplant	Statin or statin/ezetimibe combination
Age ≥ 50 years with CKD and eGFR >60 mL/minute/1.73 m^2	Statin
Age 18–49 years with CKD not on HD or history of kidney transplant with one or more of the following ■ Diabetes mellitus ■ Prior stroke ■ Known CAD ■ Estimated 10-year risk of CAD death or nonfatal MI > 10%	Statin
Dialysis-dependent CKD	No initiation of therapy

CHD, coronary heart disease; CKD, chronic kidney disease; eGFR, estimated glomerular filtration rate; HD, hemodialysis.

Adapted from Kidney Disease: Improving Global Outcomes (KDIGO) Lipid Work Group. KDIGO Clinical Practice Guideline for lipid management in chronic kidney disease. Kidney Int Suppl. 2013;3:259–305.

The 2013 ACC/AHA Blood Cholesterol guidelines do not consider CKD as a risk factor in ASCVD risk assessment and do not provide specific recommendations for statin or ezetimibe therapy in nondialysis-dependent patients. ASCVD risk assessment is performed by the CV Risk Calculator incorporating standard risk factors and pharmacotherapy is implemented according to the algorithm for primary prevention. For patients on maintenance peritoneal dialysis or hemodialysis the ACC/AHA experts felt that there was inadequate information to make a recommendation for or against the initiation or continuation of statin therapy.

CASE 8-2, QUESTION 2: Would this patient require treatment at this time?

The 2013 KDIGO Clinical Practice Guideline for Lipid Management in Chronic Kidney Disease provides guidance on lipid management and treatment for all patients with CKD (nondialysis dependent, dialysis dependent, kidney transplant recipients, and children). According to KDIGO experts, in patients with CKD who are nondialysis dependent, the relationship between LDL-C and ASCVD events is weaker than in the general population likely related to the atherogenic dyslipidemia characteristic in CKD. Thus, the measured LDL-C does not serve as an indication for treatment. KDIGO guidelines recommend that lipid therapy be guided by the absolute risk of coronary events based on patient age and stage of CKD or eGFR, regardless of baseline lipids. Statin or statin/ezetimibe therapy is recommended in nondialysis-dependent adults age ≥50 years with eGFR <60 mL/minute/1.73 m^2. In adults age ≥50 years with CKD and eGFR ≥60 mL/minute/1.73 m^2, only statin therapy is recommended. In adults age 18–49 years with CKD but not treated with chronic dialysis or kidney transplantation, statin treatment is suggested if one of the following is present: known CHD (MI or coronary revascularization), diabetes mellitus, prior ischemic stroke, or estimated 10-year incidence of coronary death or nonfatal MI >10% by the Framingham Risk Score. Statin therapy is also recommended in adult kidney transplant recipients. Therefore, according to KDIGO guidelines, S.W. may be treated with statin or statin/ezetimibe therapy.

PHARMACOLOGIC THERAPY

3-Hydroxy-3-Methyl-glutaryl Coenzyme A Inhibitors (Statins)

MECHANISM OF ACTION

Statins competitively inhibit HMG-CoA reductase, the enzyme responsible for converting HMG-CoA to mevalonate in an early, rate-limiting step in the biosynthetic pathway of cholesterol (Figs. 8-1 and 8-11). This causes decreased production of mevalonate and its subsequent conversion to cholesterol and a subsequent compensatory increase in the synthesis of LDL receptors. The increased LDL receptor density results in an increase in hepatic update of LDL-C, and to a lesser extent VLDL particles, and significantly lower levels of plasma LDL-C. In addition to the reduction in LDL-C, statins also reduce Apo B, triglyceride, and total cholesterol concentrations.[63–67]

EFFICACY

Lipid-lowering therapy for patients with ASCVD is now accepted as standard of care.[5] Beginning in the mid-1990s, the results of clinical trials with more potent statins were reported. Five of these (Scandinavian Simvastatin Survival Study (4S), Cardiovascular and Recurrent Events (CARE), the Long-Term Intervention with Pravastatin in Ischemic Disease Study (LIPID), Treating to New Targets (TNT), and Incremental Decrease in End Points through Aggressive Lipid Lowering (IDEAL)) were secondary prevention trials conducted in patients with known CHD.[68–72] In 4S, CARE, and LIPID, CHD death and nonfatal MI occurred in 13% to 22% of placebo-treated patients in the 5-year follow-up period, compared with event rates of 10% to 14% with patients on statin therapy.[68–70] Total mortality was reduced significantly in two of these trials, 4S and LIPID, that were powered to assess total mortality.

Additionally, fewer revascularization procedures were required in patients receiving statin therapy and 31% fewer strokes occurred.[73] The TNT and IDEAL trials demonstrated additional cardiovascular benefit for high-intensity versus moderate-intensity statin therapy in patients with stable CHD. These trials randomly assigned patients to receive either high-dose atorvastatin 80 mg versus atorvastatin 10 mg or simvastatin 20 mg with an approximate follow-up period of 5 years. In both trials, more intensive lowering of LDL-C to significantly less than 100 mg/dL was associated with a reduction in CHD.[71,72] The further reductions in the incidence of heart attacks, revascularizations, and ischemic strokes with more intensive lowering of LDL-C with statins compared with less-intensive statin regimens was verified in a recent meta-analysis of randomized trials. An additional 38.6-mg/dL reduction of LDL-C in patients on high-intensity therapy was associated with a 38% relative reduction in major vascular events ($p < 0.0001$).[73]

The Heart Protection Study (HPS)[74] extended the results of earlier secondary prevention statin trials (4S,[68] CARE,[69] LIPID[70]). The HPS included 20,536 patients with a history of CHD or cerebrovascular disease (stroke or transient ischemic attacks), peripheral vascular disease, or diabetes not considered by their general practitioner to have a clear indication for statin therapy because of relatively low baseline cholesterol levels (mean LDL-C 131 mg/dL).[74] A reduction in CHD events was achieved in both men and women; in all age groups, including those aged 75 to 85 years; and regardless of the baseline LDL-C, including those with initial levels less than 100 mg/dL.

Trials in patients with acute coronary syndromes (ACS) have also demonstrated CHD risk reduction. The Myocardial Ischemia Reduction with Aggressive Cholesterol Lowering (MIRACL) study randomly assigned patients presenting to the hospital with unstable angina or non–Q-wave MI to statin therapy or placebo for 4 months. This resulted in a 24% reduction in symptomatic ischemia requiring emergency hospitalization and a 60% reduction in nonfatal strokes in those receiving the statin.[75,76] More recently, the Pravastatin or Atorvastatin Evaluation and Infection Therapy—Thrombolysis in Myocardial Infarction (PROVE-IT) is considered a landmark trial that demonstrated superior cardiovascular event lowering when high-intensity statin therapy (atorvastatin 80 mg) was implemented within 10 days of ACS versus moderate-intensity (pravastatin 40 mg) statin therapy.[77] After 2 years of treatment, mean LDL-C levels in patients randomly assigned to receive atorvastatin 80 mg and pravastatin 40 mg were 62 and 95 mg/dL, respectively. The composite cardiovascular endpoint (death from any cause, MI, documented unstable angina requiring rehospitalization, revascularization, and stroke) was significantly reduced by 16% with high-intensity atorvastatin compared with moderate-intensity pravastatin.[77] Data from the National Registry of Myocardial Infarction 4 demonstrated that early initiation of statins in the acute setting (with the first 24 hours of an acute MI) was associated with a significantly lower rate of early complications and in-hospital mortality.[78] Additionally, discontinuation of statin in patients who present with an ACS is associated with increased event rates above those who are statin naive.[79,80]

PHARMACOKINETICS/PHARMACODYNAMICS

The currently available statins are atorvastatin, fluvastatin, lovastatin, pitavastatin, pravastatin, rosuvastatin, and simvastatin. These agents possess different pharmacokinetic properties that may play a role in their efficacy and safety.

Three statins are derived from fungi (simvastatin, pravastatin, and lovastatin),[81–83] while the others (atorvastatin, rosuvastatin, pitavastatin, and fluvastatin) are synthetic.[84–87] Lovastatin and simvastatin are prodrugs and must be converted to their active form to exert a pharmacologic effect. Rosuvastatin and atorvastatin have the longest half-lives of 19 and 14 hours, respectively, which enables longer inhibition of the HMG-CoA enzyme and greater LDL-C reductions compared to other agents.[84,86] Both of these agents lower LDL-C by a mean of approximately 60% at maximum doses (rosuvastatin 40 mg daily and atorvastatin 80 mg daily). The long half-life also allows for administration at any time of day rather than at bedtime for maximum effect, which is recommended for simvastatin, lovastatin, pravastatin, and fluvastatin.[81–83,85] Although pitavastatin has a shorter half-life (12 hours) than rosuvastatin and atorvastatin it may also be taken at any time of day.[84,86] The administration of the shorter acting agents at bedtime is important because cholesterol biosynthesis occurs at its highest rate in the evening hours, thus allowing these agents to have the greatest effect on HMG-CoA reductase inhibition and on lowering of LDL-C. However, with extended-release (ER) formulations of lovastatin and fluvastatin, bedtime administration is less important.[81–88]

The amount of statin that reaches the systemic circulation is relatively small. Bioavailability ranges from less than 5% with lovastatin and simvastatin to 51% with pitavastatin (oral solution). Pravastatin, fluvastatin, and rosuvastatin are hydrophilic agents and may have less tissue distribution and result in less muscle toxicity. However, this aspect is more theoretical than it is clinically valid. All statins are eliminated primarily by the liver, with substantial biliary excretion. However, several statins require dose adjustments in patients with significant renal insufficiency (Table 8-8).[81–88]

ADVERSE EFFECTS

Statins are generally well tolerated. The most common adverse effects reported include muscle pain and weakness (myalgias), headache, GI symptoms, including dyspepsia, flatus, constipation, and abdominal pain, and skin rashes.[81–91] These symptoms are usually mild and often dissipate with continued therapy. Less common adverse effects include myopathy, elevated hepatic transaminases, and diabetes. Cognitive dysfunction may be potentially associated with statin therapy but this has not yet been demonstrated to be causally related to statin treatment.

Muscle-related adverse effects associated with statins are divided into three different types based on symptoms and the presence or absence of creatine kinase (CK) elevations. These include myalgias, myopathy, and rhabdomyolysis. Myalgias are the most commonly reported muscle symptoms with an incidence of around 32%.[92] Myalgias are defined as muscle aches or weakness without CK elevations. This adverse effect is the most common reason for patients to discontinue statin therapy.[92]

Table 8-8

Dosing of Statins in Patients with Renal Insufficiency[81–88]

Statin	Creatinine Clearance 30–50 mL/minute	Creatinine Clearance 15–29 mL/minute	Creatinine Clearance <15 mL/minute or on Hemodialysis
Atorvastatin	Doses up to 80 mg may be used	Doses up to 80 mg may be used	Doses up to 80 mg may be used
Fluvastatin	Doses up to 80 mg may be used	Doses up to 40 mg may be used	Doses up to 40 mg may be used
Lovastatin	Doses up to 80 mg may be used	Doses up to 40 mg may be used	Doses up to 40 mg may be used
Pitavastatin	Doses up to 2 mg may be used	Doses up to 2 mg may be used	Doses up to 2 mg may be used
Pravastatin	Doses up to 40 mg may be used	Doses up to 40 mg may be used	Doses up to 40 mg may be used
Simvastatin	Doses up to 80 mg may be used	Doses up to 20 mg may be used	Doses up to 20 mg may be used
Rosuvastatin	Doses up to 40 mg may be used	Doses up to 10 mg may be used	No data

Myopathy is defined as the presence of myalgias, including aches, soreness, or weakness, and an increase in serum CK more than 10 times the upper lipid of normal (ULN). Myopathy occurs in approximately 0.1% to 1% of patients and is a dose-dependent effect. If myopathy is present, a careful history is necessary to rule out usual causes (i.e., trauma, increased physical activity). Rhabdomyolysis is defined as a CK of at least 10 times the ULN with an elevated serum creatinine and symptoms requiring treatment.[93] Rhabdomyolysis is the least common of the muscle-related adverse effects, but can be life threatening with acute renal failure, cardiac arrest, or arrhythmias due to severe electrolyte abnormalities. Most cases of rhabdomyolysis have occurred with high doses of statins, in patients with impaired renal or hepatic function, in older individuals, or when statins are used in combination with interacting drugs. The most common areas affected are in the belly of larger muscles. It is important to distinguish between this and joint pain that may be associated with arthritis.

Simvastatin at a dose of 80 mg daily is associated with the highest incidence of rhabdomyolysis among the statins agents. However, this dose is no longer recommended by the US Food and Drug Administration (FDA) and the ACC/AHA cholesterol guideline.[5,81]

Management of statin-associated muscle adverse effects can be challenging. Routine monitoring of CK levels in asymptomatic patients is unnecessary. However, unexplained symptoms of muscle aches, weakness, or soreness should prompt evaluation of CK and other potential underlying etiologies. Myopathy is more likely to occur with high systemic concentrations of statin and when there are underlying risk factors (e.g., age > 80 years, severe CKD, hypothyroidism, trauma, interacting medications, or flu-like syndromes). If a patient develops signs and symptoms consistent with myopathy, statin therapy should be withdrawn until CK levels return to normal. If rhabdomyolysis is diagnosed, statin therapy should be discontinued immediately and etiology determined. Re-challenge of a statin may be considered if the cause was secondary to an interacting medication or other underlying cause that can be identified and corrected. Occasionally, symptoms of myalgia are bothersome or intolerable to the patient, even when the CK level is normal or elevated less than 10 times the ULN. In these cases, the statin should be discontinued. Once symptoms subside, statin therapy can be restarted at the same or reduced dose, or with a different statin. Alternate day and even once-weekly dosing of statins have been used in patients who have statin intolerance caused by myopathy.[94] However, these alternative regimens have not been evaluated in cardiovascular outcome trials.

Statins may also cause an elevation in transaminase enzyme levels of more than 3 times the ULN in 1% to 1.5% of patients in a dose-dependent manner. The transaminase level will often return to normal spontaneously in 70% of cases even with continued statin therapy.[93] Elevations in transaminases will also return to normal if the statin is discontinued. Rechallenge with the same or a different statin after enzymes have returned to normal limits is acceptable. If the medication is tolerated on rechallenge, it can be continued; recurrence of transaminase elevation warrants further evaluation of other potential causes. It is recommended that prior to initiating statin therapy patients should have baseline liver function tests performed. The report of the NLA Statin Safety Task Force recommends that if ALT or AST is 1 to 3 times the ULN during statin therapy, there is no need to discontinue the statin.[93] If ALT or AST exceeds 3 times the ULN during statin therapy, monitor the patient and repeat the transaminase measures. There is no need to discontinue the statin. If a patient’s transaminase levels continue to rise or if there is further objective evidence (i.e., hepatomegaly, jaundice, elevated direct bilirubin, related symptoms) of liver injury, the statin should be discontinued. The estimated incidence of statin-associated liver failure is 1 per million person-years of use.[95] There is evidence that patients with chronic liver disease, nonalcoholic fatty liver disease, or nonalcoholic steatohepatitis may safely receive statin therapy.[96]

In 2012, the FDA required an update to the statin prescribing labeling to include information regarding a potential increased risk of reversible cognitive impairment, to include memory loss. Some case reports have suggested that the statins may cause cognitive impairment or memory loss.[97] However, data from randomized controlled trials have failed to show an association and some data even suggest a beneficial effect on the progression of Alzheimer disease.[74,98,99] Therefore, if a patient presents with cognitive deficits, he should first undergo an evaluation to identify other potential causes. If the statin is suspected, it is reasonable to consider discontinuing therapy for up to 3 months and monitor for improvment.[93] If improvement is noted, then a speculation may be made that the statin was the cause. However, one must carefully balance the decision to discontinue the statin due to the proven benefit of these agents. Consideration should be given to perhaps reintroduce a different statin or a different statin dose and monitor for recurrence of deficits. Additionally, because improvement in cognitive function is subjective, an objective test such as a Mini Mental State Exam (MMSE) should be considered prior to discontinuation and repeated after discontinuation to assess for any changes.

CASE 8-3

QUESTION 1: M.T. is a 56-year-old white female who presents for new patient evaluation with a 10-year history of type 2 diabetes and hypertension. Current medications include metformin, lisinopril, and chlorthalidone. She currently smokes about 1/2 pack of cigarettes/day, but is considering a quit date. She reports that she struggles with weight management (BMI 33.8 kg/m^2) and has difficulty with exercise due to previous knee injury and a torn rotator cuff. She has a strong family history of premature ASCVD, diabetes, hyperlipidemia, and obesity. Her father underwent coronary artery bypass grafting at age 51. Her mother suffered a mild stroke at age 62, but has no residual deficits. She has four siblings of which two have known CHD. On physical exam her BP is 148/88; bilateral carotid bruits; cardiac exam unremarkable; abdominal bruit; peripheral pulses 1+ bilaterally; no tendon xanthomas, corneal arcus, or xanthelasmas. Her initial laboratory results demonstrate the following:

Total cholesterol, 273 mg/dL
HDL-C, 43 mg/dL
LDL-C, 158 mg/dL
TGs, 360 mg/dL
$HgbA_{1c}$, 8.2%

What are your initial recommendations for lipid management for M.T.?

All available guidelines for the management of dyslipidemia and diabetes recommend lifestyle counseling as the foundation of therapy. M.T.’s BMI is consistent with obesity and she has inadequately controlled diabetes and hypertension. Nutrition counseling and weight management will be critical to improve control of these important ASCVD risk factors. Tobacco cessation counseling, referral to a cessation program, and possible pharmacotherapy and/or nicotine replacement therapy are important in this very high-risk patient with a strong family history of premature ASCVD. Given the patient's ongoing knee and shoulder pain, her ability to engage in significant aerobic activity may be limited until successful weight loss is achieved.

According to ACC/AHA, NLA, and ADA recommendations for management of dyslipidemia M.T. qualifies for statin therapy in a high-risk diabetic. Her 10-year ASCVD risk by the ACC/AHA CV Risk Calculator is 27.2% and high-intensity statin is indicated by the ACC/AHA treatment algorithm. Patients with diabetes and two or more other major ASCVD risk factors are considered to be at very high risk by the NLA and lipid-lowering therapy is recommended with treatment goals of non–HDL-C < 100 mg/dL and LDL-C < 70 mg/dL. The ADA recommends statin therapy in all patients between the ages of 40 to 75 with type 1 or type 2 diabetes. The intensity of statin therapy is based upon the patient's 10-year ASCVD risk by the ACC/AHA CV Risk Calculator. High-intensity statin is considered reasonable in patients with 10-year risk ≥7.5%. Thus, the recommendation for high-intensity statin therapy for M.T. is consistent across all three of these US guidelines.

CASE 8-3, QUESTION 2: M.T. is started on atorvastatin 40 mg but within the next 3 months returns to clinic complaining of joint and muscle symptoms, noting that her knees and shoulder are more painful. How would you approach the evaluation of possible statin-related muscle symptoms?

Statin-related muscle symptoms present a significant challenge to clinicians, though the prevalence of true statin intolerance is likely quite low. A systematic approach to possible statin intolerance is required to confirm the diagnosis, particularly in a very high-risk patient like M.T. The ACC/AHA guideline and NLA recommendations provide similar strategies for patient evaluation and management and these recommendations have been incorporated into the ACC Statin Intolerance app for all mobile devices as well as a web-based version.

It is important for clinicians to take a careful musculoskeletal history and review of systems and document patient complaints prior to initiation of statin therapy. As reported by M.T., patients may report baseline muscle and joint symptoms that have varied in severity and frequency prior to lipid management. Following initiation of statin therapy, patient's muscle symptoms should be compared to those at baseline evaluation to determine if complaints are new or merely coincidental exacerbations of prior existing symptoms. True statin-related myalgias are typically symmetric and are described as aching, soreness, stiffness, tenderness, weakness, or cramping of large proximal muscle groups. Tingling, numbness, sharp or stabbing pain, twitching, nocturnal cramps, arthralgias/arthritis, or unilateral symptoms are less likely to be statin related. Clinicians should consider factors that may increase the risk for statin-related muscle symptoms, such as heavy exercise or exertion, dehydration, substance abuse, frailty, low BMI, female gender, multiple or serious comorbidities, renal insufficiency, hepatic dysfunction, or drug interactions. Other potential primary causes of muscle symptoms should be evaluated such as hypothyroidism, vitamin D deficiency, trauma, previous or new primary muscle diseases, rheumatologic disorders, metabolic disorders (adrenal insufficiency, hypoparathyroidism, Cushing syndrome), or peripheral arterial disease.

CASE 8-3, QUESTION 3: What recommendations would you give the patient regarding continuation of statin therapy?

The ACC/AHA and NLA recommend temporary discontinuation of statin when a patient reports muscle symptoms that they believe are related to treatment. Statin-related complaints usually resolve within a few days to 2 weeks, though there have been rare case reports of persistent myopathy following discontinuation of statin therapy. When symptoms have resolved and the patient is asymptomatic, treatment with the same statin at original or lower dose is reinitiated to determine if the symptoms are definitively related to statin. If muscle complaints recur, it is assumed that symptoms may be related to drug therapy and statin should be discontinued. Most algorithms for evaluation and management of possible statin intolerance recommend a trial of at least two to three statins, with discontinuation and re-challenge if the patient again reports muscle-related symptoms.

The seven currently available statins differ in metabolism, half-life, and lipophilicity, and some providers recommend that the second (or third) statin prescribed in a patient with possible statin intolerance be chosen based on characteristics that differ from the initial agent. There is no trial evidence that this strategy is effective. There have been a number of smaller trials evaluating the potential benefits of ubiquinone or coenzyme Q10 in patients with possible statin-related muscle symptoms, but the results have been inconsistent.

If a patient has failed a systematic challenge/re-challenge approach with two to three statins, guidelines suggest consideration of non-statin therapies such as ezetimibe, BASs ,or PCKS9 inhibitors.[100]

DIABETES

Statins have been associated with an increased risk of type 2 diabetes. A review of 13 trials involving 19,140 patients showed a 9% relative increased risk for the incidence of diabetes in those taking statins compared to placebo. This equates to approximately one new case of diabetes for every 255 patients treated over a 4-year

---

period.[101] A meta-analysis of five trials comparing high-dose versus low-dose statins showed a 12% increased relative risk for incident diabetes over a 2- to 5-year follow-up in those patients who received higher doses of statins.[102] Based on the data, there appears to be an increased risk of developing diabetes, albeit small. However, due to the demonstrated clinical benefit of statin therapy, the benefit clearly outweighs the risk of developing diabetes and statin therapy should not be avoided due to the concern for this adverse effect.

Overall, the incidence of adverse effects with statins varies with myalgia being the most common. When choosing a statin as well as a statin dose, one must consider the various pharmacokinetic characteristics of that statin, the patients' comorbid conditions, and concomitant medications to minimize risk.

PLACE IN THERAPY

Statins are considered first-line pharmacologic therapy for prevention of ASCVD events. They have demonstrated significant reductions in morbidity and mortality across many patient populations.[68–72,103,104] Statin therapy should be initiated before or simultaneously with therapeutic lifestyle modifications.[5]

The initial dose of statin is determined by certain criteria that then place them into any of the four statin benefit groups. The criteria are based on age, presence or absence of ASCVD, presence or absence of diabetes, LDL-C level, and their estimated risk based on the Pooled Cohort Equation.[5] High-intensity statin therapy is recommended in the following patient populations: patients <75 years of age who have clinical ASCVD; patients over 21 years of age and an LDL-C of >190 mg/dL; or patients with diabetes (type 1 or 2) between the ages of 40 and 75 with an estimated 10-year ASCVD risk of >7.5%. Moderate-intensity therapy is recommended in patients >75 years of age if not a candidate for high intensity; LDL-C > 190 mg/dL (if not a candidate for high intensity); type 1 or type 2 diabetes and age 40 to 75 years; or a 10-year ASCVD risk of >7.5% and age 40 to 75 years. The later population may be initiated on high-intensity therapy if clinically indicated. The intensity of doses of the various statins is outlined in Table 8-3.[5] Of note, in patients with LDL-C > 190 mg/dL, combination therapy with a non-statin agent may be needed to achieve additional LDL-C lowering if desired.

There are two patient populations for which there are limited data on the benefit of statin therapy. These include patients with ASCVD and heart failure (New York Heart Association Class II to IV) and patients on chronic hemodialysis. There are currently no recommendations to initiate statin therapy in these patient populations.[5]

In addition to their ability to lower LDL-C, statin also have many "pleiotropic" effects that play a role in patients with ASCVD, independent of their ability to lower LDL-C. These effects include improvement in endothelial function, plaque stabilization, antithrombotic effects, anti-inflammatory, antioxidant effects, increased nitric oxide bioavailability, and reduced plaque progression.[105]

Although well demonstrated as beneficial in patients with established CHD, this benefit in primary prevention is less well defined. In patients without CHD, statins have not been shown to reduce mortality. They have demonstrated a lowering of future vascular events over a time frame of 5 to 10 years, albeit small. As a result, prescribing statins in patients without ASCVD but who are between the ages 40 to 75 years with an estimated ASCVD risk of ≥7.5% remains controversial.

DRUG INTERACTIONS

Drug interactions with statins that result in higher blood levels of the statin or an active metabolite can increase the risk of myositis. Statins that depend on the cytochrome P-450 (CYP) 3A4 enzyme system to be metabolized are most vulnerable to this interaction (i.e., lovastatin, simvastatin, and to a lesser extent atorvastatin). Fluvastatin is primarily a substrate of the 2C9 isoenzyme and, to a lesser extent, 2C8 and 3A4 and, therefore, is more vulnerable to interactions with drugs that directly inhibit CYP2C9 or act as competitive inhibitors (substrates) for this alternative system. Pravastatin, pitavastatin, and rosuvastatin are not extensively metabolized by the CYP enzyme system.[85–87] Rosuvastatin is metabolized minimally (about 10%) with CYP2C9 and CYP2C19 being the primary isoenzymes involved. Pitavastatin is marginally metabolized by CYP2C9 and to a lesser extent by CYP2C8. The major metabolite in human plasma is lactone, which is formed via glucuronidation by uridine 5′-diphospho-glucuronosyltransferases UGTA3 and UGT2B7. Pravastatin undergoes isomerization in the gut to a relatively inactive metabolite. Variability of gastric metabolism has been shown to be associated with the LDL-C–lowering effects of pravastatin.[106] Therefore, rosuvastatin and pravastatin have the lowest potential for interaction with medications that inhibit the CYP metabolic pathways. Some of the most commonly encountered medications that interact with statins by inhibiting the CYP3A4 enzyme system are azole antifungals (itraconazole, ketoconazole, and miconazole), certain calcium-channel blockers (diltiazem and verapamil), macrolide antibiotics (clarithromycin and erythromycin), protease inhibitors (e.g., ritonavir), grapefruit juice (>1 quart), cyclosporine, and antidepressants (nefazodone). Drugs that are substrates for the CYP3A4 system include certain benzodiazepines (alprazolam, midazolam, triazolam), calcium-channel blockers (especially diltiazem), carbamazepine, cisapride, cyclosporine, estradiol, felodipine, loratadine, quinidine, and terfenadine. When these substrate drugs are used together with simvastatin or lovastatin (and to a lesser extent atorvastatin), systemic blood levels of the statin may be increased because of competitive inhibition of the CYP3A4 enzymes, and this may increase the risk for myositis.

Added caution should also be exercised when adding gemfibrozil with a statin to treat patients who also have elevated triglyceride levels. Gemfibrozil interferes with the glucuronidation of statins, thereby interfering with their renal clearance. This impact may be minimal or up to a three- to fourfold increase in statin levels depending upon the specific agent.[107–116] Due to the significance of this interaction, fenofibrate is the preferred fibric acid derivative to use in combination with statins. However, gemfibrozil may be used in combination with certain statins if clinically indicated.[86,109–114,117,118] A list of select statin drug interactions is presented in Table

8-9.

CASE 8-4

QUESTION 1: J.G. is a 63-year-old white woman who implemented lifestyle modifications for her dyslipidemia 7 months ago and is in clinic for follow-up. She has a history of gout, chronic nonischemic HF (LVEF 26%), and diabetes (diet controlled) as well as a 20 pack-year smoking history (quit 5 years ago). Her medications include lisinopril, furosemide, metoprolol succinate 25 mg once daily. Her vital signs include BP 124/80 mm Hg and HR 75 beats/minute. Her laboratory results are as follows: HDL-C 64 mg/dL, LDL-C 101 mg/dL, TG 98 mg/dL, and TC 185 mg/dL.

What is her 10-year ASCVD risk based on the calculator?

The components of the risk calculator that impact J.G. include her age, gender, total cholesterol, HDL cholesterol, and diabetes. She does not have hypertension and smoking does not count as a risk factor due to the fact that she is not a current smoker. Therefore, her 10-year ASCVD risk is 7.1%.

CASE 8-4, QUESTION 2: Based on her risk, what is the most appropriate next step for J.G.?

Table 8-9

Select Drug Interactions with Statins[81–88,118]

	Contraindicated Medications	Medications with Dose Limits	Maximum Dose of Statin When Used in Combination
Atorvastatin	Tipranavir plus ritonavir Telaprevir	Boceprevir Clarithromycin Itraconazole Nelfinavir Cyclosporine/tacrolimus/everolimus/sirolimus	Do not exceed 40 mg daily Do not exceed 20 mg daily Do not exceed 20 mg daily Do not exceed 40 mg daily Do not exceed 10 mg daily
Fluvastatin		Fluconazole Itraconazole Cyclosporine	Do not exceed 20 mg daily Do not exceed 20 mg daily Do not exceed 40 mg daily
Lovastatin	Boceprevir Clarithromycin Cyclosporine Erythromycin	Amiodarone Danazol Diltiazem Verapamil	Do not exceed 40 mg daily Do not exceed 20 mg daily

	Gemfibrozil Ketoconazole Nifazodone HIV protease inhibitors Itraconazole Posaconazole Telaprevir Telithromycin Voriconazole	Dronedarone Lomitapide	Do not exceed 20 mg daily Do not exceed 20 mg daily Do not exceed 10 mg daily Do not exceed 20 mg daily
Pitavastatin		Rifampin	Do not exceed 2 mg daily
Pravastatin		Clarithromycin Cyclosporine/tacrolimus/everolimus/sirolimus	Do not exceed 40 mg daily Do not exceed 20 mg daily
Rosuvastatin		Cyclosporine/tacrolimus/everolimus/sirolimus Gemfibrozil Lopinavir/ritonavir Atazanavir/ritonavir	Do not exceed 5 mg daily Do not exceed 10 mg daily Do not exceed 10 mg daily Do not exceed 10 mg daily
Simvastatin	Boceprevir Clarithromycin Cyclosporine Erythromycin Gemfibrozil Itraconazole Ketoconazole HIV protease inhibitors Itraconazole Posaconazole Telaprevir Telithromycin Voriconazole	Amiodarone Amlodipine Diltiazem Verapamil Dronedarone Lomitapide Ranolazine	Do not exceed 20 mg daily Do not exceed 20 mg daily Do not exceed 10 mg daily Do not exceed 10 mg daily Do not exceed 10 mg daily Do not exceed 20 mg daily Do not exceed 20 mg daily

J.G. falls into the statin benefit group of a diabetic with a 10-year risk of <7.5%. The guidelines recommend that she be initiated on moderate-intensity statin therapy. Therefore, any statin dose within this category that would lower LDL-C by 30% to <50% would be appropriate. At this time she is not a candidate for a high-intensity statin, despite having diabetes. The decision is made to initiate simvastatin 40 mg daily.

CASE 8-4, QUESTION 3: Four months later, J.G. is admitted to the hospital with atrial fibrillation and is started on amiodarone and apixaban 5 mg twice daily. What medication modifications should be done to J.G.'s medication regimen at this time?

The addition of amiodarone to her medication regimen necessitates a reduction in her dose of simvastatin to 20 mg daily. This dose is still within moderate-intensity range and is acceptable. The other option would be to switch her to different statin that is either not metabolized by CYP3A4 or metabolized to a lesser extent than simvastatin. Reasonable choices of statins would be pravastatin 40 to 80 mg daily, fluvastatin 40 mg BID or XL 80 mg daily, atorvastatin 10 to 80 mg daily, pitavastatin 2 to 4 mg daily, lovastatin 40 mg daily, and rosuvastatin 5 to 40 mg daily.

CLINICAL PEARLS

Approximately 50% of patients discontinue statin therapy within 6 months of initiation and only one-third are still adherent after

---

a year. Therefore, it is important to minimize adverse effects and be able to identify if the statin may be the cause. The incidence of statin intolerance is estimated to be 5% to 10% among statin-treated patients. However, in light of the new AHA/ACC cholesterol guidelines, 13 million more individuals have become eligible for statin therapy and the overall prevalence of statin intolerance in the United States is likely to increase. Diagnosing statin intolerance is challenging as no universal definition exists. The NLA has several definitions of statin intolerance, but the one most clinically useful is the inability to tolerate at least two statins. The two statins should be one that was prescribed and taken at the lowest starting dose and another one that was taken at any dose. In addition to the two statins challenge, patients need to have either objectionable symptoms, or abnormal laboratory values, which are temporally related to statin therapy and reverse upon statin discontinuation and recur upon reinitiation. The ACC has also developed an application called “ACC Statin Intolerance App” designed to assist providers in making the diagnosis of true statin intolerance. The application provides the clinician with a systematic strategy for evaluation of symptoms, management recommendations, as well as information regarding statin characteristics and drug interactions. This application is available on the web at **http://tools.acc.org/StatinIntolerance**, via Itunes at **https://itunes.apple.com/us/app/statin-intolerance/id985805274?mt=8** or via Google Play at **https://play.google.com/store/apps/details?id=org.acc.StatinIntolerance&hl=en.**

Routine monitoring of liver function tests is no longer recommended during statin treatment. However, patients should be made aware of symptoms that may indicate potential hepatic disease such as flu-like symptoms, fatigue, sluggishness, anorexia, weight loss, right upper quadrant pain, yellowing of eyes, or jaundice.

All patients should have a fasting lipid panel prior to statin initiation. The ACC/AHA guidelines for monitoring of statin therapy recommend a follow-up lipid panel in 4 to 12 weeks following statin initiation to assess patient adherence and response to therapy and then every 3 to 12 months as clinically indicated.[5]

Coenzyme Q10 is an isoprenoid that plays a unique role in cellular electron transport and energy synthesis. It is essential for the normal functioning of muscles. Statins have been shown to reduce blood levels of coenzyme Q10 but muscle tissue concentrations are unaffected. Evidence of the value of supplementing coenzyme Q10 in patients experiencing statin-induced myopathy has been mainly anecdotal. However, the risk of taking CQ10 is relatively small and may be considered in patients complaining of muscle aches in the absence of symptoms that are concerning for more serious muscle-related disease.

Cholesterol Absorption Inhibitor (Ezetimibe)

MECHANISM OF ACTION

Cholesterol that is ingested in the diet and circulated through the bile from the liver is actively reabsorbed in the intestines. Once transported across the intestinal lumen into the enterocyte, it is combined with TG and apo B-48 to form chylomicron particles that transport the lipids through the lymphatic system to the hepatocyte. The TG and cholesterol can then be packaged into VLDL particles and secreted into the systemic circulation (Fig. 8-12).

In the small intestine the Niemann–Pick C1L1 (NPC1L1) transporter is responsible for the uptake of dietary and biliary cholesterol into the small intestine. Ezetimibe interferes with the active absorption of cholesterol and plant sterols from the intestinal lumen into the enterocyte by binding to and inhibiting this transporter. By interfering with the absorption of cholesterol, about 50% less cholesterol is transported from the intestines to the liver by the chylomicrons. This causes an upregulation of hepatic LDL receptors and increased clearance of circulating VLDL and LDL particles. There is also an upregulation in hepatic cholesterol synthesis, which is diverted to the intestines via the bile to replenish the cholesterol available for intestinal absorption processes. The net effect of the inhibition of the NPC1L1 transporter is an approximate 70% increase in GI sterol excretion, a 50% reduction in hepatic cholesterol concentration, a 90% increase in hepatic cholesterol synthesis, and an approximate 20% increase in LDL-C clearance from the systemic circulation via upregulated LDL receptors.[119,120]

Ezetimibe also inhibits the absorption of sitosterol and other plant sterols from the gut, resulting in about a 40% reduction in blood sitosterol levels. The occurrence of sitosterolemia is rare, but is associated with a high CHD risk. Ezetimibe provides one of the first effective treatments for this rare disorder.

EFFICACY

The ENHANCE (Ezetimibe and Simvastatin in Hypercholesterolemia Enhances Atherosclerosis Regression) trial was a randomized, double-blind, placebo-controlled trial comparing simvastatin 80 mg combined with ezetimibe 10 mg versus simvastatin 80 mg alone administered once daily in 720 patients with HeFH.[121] The primary outcome was the change in mean carotid intima media thickness (CIMT) after 24 months of treatment. This trial was not statistically powered to determine differences in vascular disease event rates between treatments because of the short study duration and the small number of patients. Mean baseline LDL-C (319 vs. 318 mg/dL, respectively) and CIMT (0.69 vs. 0.70 mm, respectively) were similar between the treatment groups. The percent change in LDL-C was significantly ($p < 0.01$) greater in the simvastatin–ezetimibe group (−55.6%) compared with the simvastatin–placebo group (−39.1%). However, there was no regression in CIMT in either treatment group, and the mean changes in the CIMT were similar between the treatment groups ($p = 0.29$) after 24 months of treatment. Why was there not a greater change in CIMT in patients randomly assigned to the simvastatin–ezetimibe group compared with the simvastatin–placebo group given that these patients had a greater reduction in LDL-C? Before randomization, approximately 80% of the patients in both treatment groups were receiving statin therapy. Moreover, these patients had thinner or near-normal CIMT at baseline when compared with patients with HeFH studied in previously published statin trials[122,123] that did demonstrate reduced CIMT with high-dose statin therapy. Collectively, this suggests that the patients studied in the ENHANCE trial were aggressively managed for their cholesterol for many years, resulting in the depletion of vascular wall lipids. Therefore, additional aggressive treatment would unlikely result in further regression of an already lipid-depleted carotid vascular wall. In contrast, Avellone et al.[124] recently demonstrated that ezetimibe combined with simvastatin caused a significant reduction in CIMT in FH patients with and without a history of MI. These patients had similar mean baseline LDL-C (301 mg/dL) to patients studied in the ENHANCE trial; however, baseline CIMTs in this trial were much larger (1.82 mm without a history of MI, and 1.98 mm with a history of MI) than those observed in the ENHANCE trial and were consistent with CIMTs in patients with FH who have not been aggressively treated.

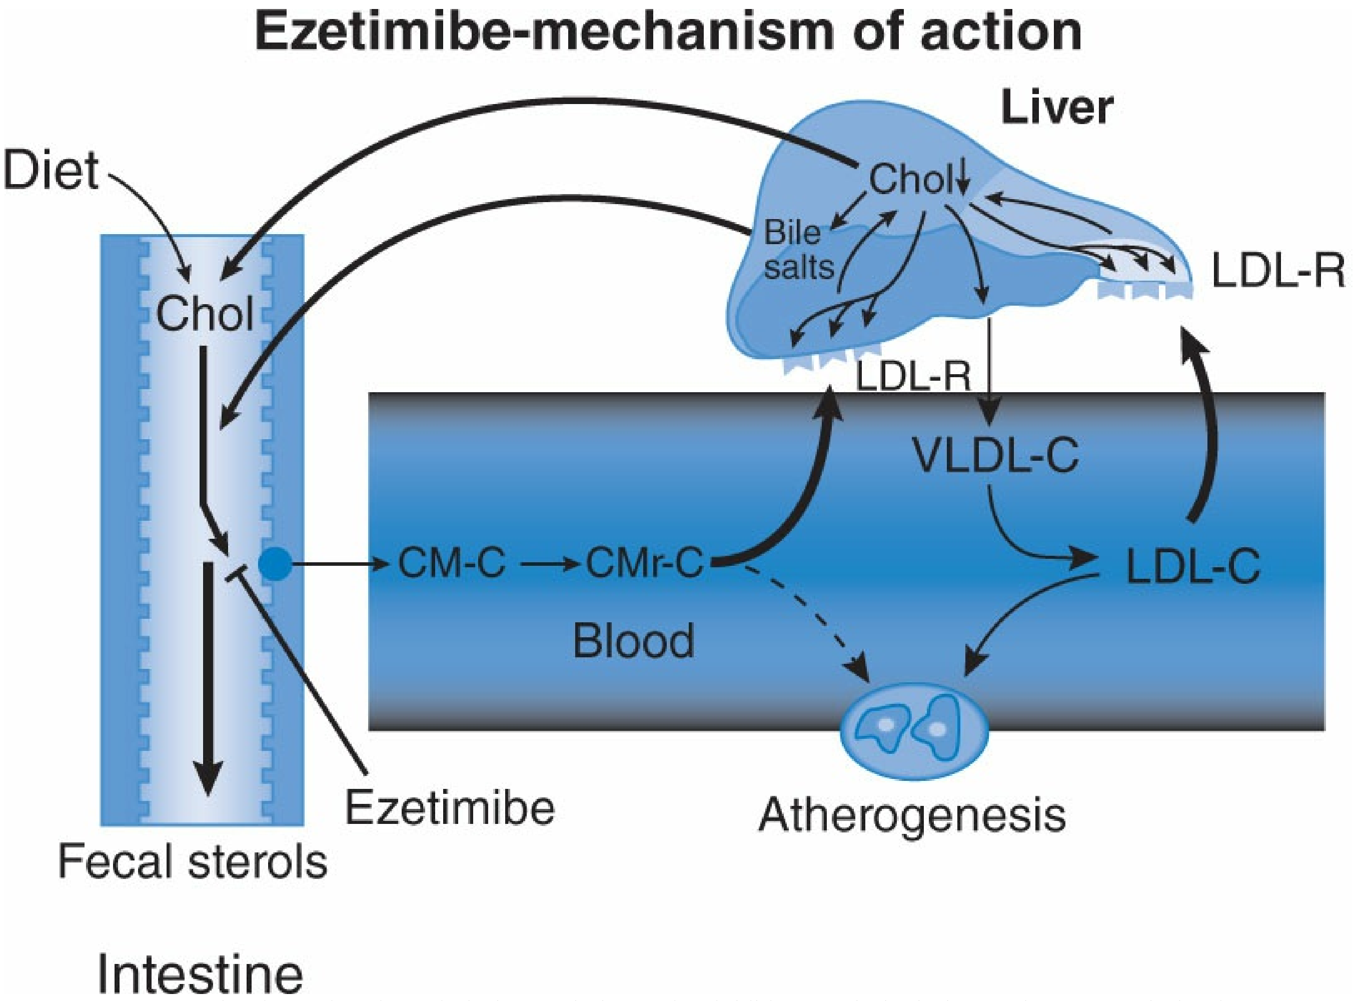

Figure 8-12 Mechanism of action of cholesterol absorption inhibitors. Chol, cholesterol; CM-C, chylomicron cholesterol; CMr-C, chylomicron remnant cholesterol; LDL-C, low-density lipoprotein cholesterol; LDL-R, low-density lipoprotein real; VLDL-C, very low-density lipoprotein cholesterol.

When ezetimibe was combined with simvastatin versus placebo in 1,873 patients with mild to moderate, asymptomatic aortic stenosis and no previous history of vascular disease, diabetes mellitus, or any other indications for cholesterol-lowering therapy, significantly fewer patients treated with simvastatin–ezetimibe (15.7%) had ischemic cardiovascular events compared with the placebo group (20.1%), mainly related to a reduction in coronary artery bypass grafting ($p = 0.02$).[125]

The incremental benefits of adding ezetimibe to statin therapy were evaluated in the IMProved Reduction of Outcomes: Vytorin Efficacy International Trial (IMPROVE IT).[126] This was a multicenter, randomized, double-blinded trial involving 18,144 patients that sought to determine the clinical benefit and safety of combination therapy with ezetimibe and simvastatin compared to simvastatin monotherapy in high-risk patients presenting with ACS. This was the first large trial to evaluate the clinical efficacy of adding a non-statin (ezetimibe 10 mg/day + simvastatin 40 mg/day) to statin (simvastatin 40 mg/day) monotherapy. The primary endpoint was cardiovascular death, nonfatal MI, rehospitalization for unstable angina, coronary revascularization ≥30 days following randomization, or stroke. Over a median follow-up of 57 months, the addition of ezetimibe to simvastatin 40 mg reduced the primary endpoint by 6.4% when compared with patients who received simvastatin alone ($p = 0.016$). The absolute reduction in risk over 7 years was 2.0%. The reduction in the primary endpoint was largely driven by a statistically significant reduction in the risk of MI and ischemic stroke. Overall, there was a significant 10% reduction in the risk of cardiovascular death, nonfatal MI, or nonfatal stroke. However, there was no difference in all-cause mortality between the two treatment groups. The average LDL-C during the study was 53.7 mg/dL in the simvastatin–ezetimibe group, compared to 69.5 mg/dL in the simvastatin monotherapy group ($p < 0.001$). The results of this study support the "lower-is-better" premise for LDL-C.[126]

PHARMACOKINETICS/PHARMACODYNAMICS

Ezetimibe is a prodrug that is rapidly conjugated to an active phenolic glucuronide (ezetimibe-glucuronide).[120] The drug is primarily metabolized in the small intestine via glucuronide conjugation with subsequent renal and biliary excretion. The elimination half-life is approximately 22 hours. Absorption is not affected by food and ezetimibe may be administered at any time of day without regard to meals. There are no dose adjustments necessary for patients with renal impairment or with mild hepatic insufficiency.

ADVERSE EFFECTS

Ezetimibe is well generally well tolerated with minimal adverse effects. The adverse effects that are the most reported include diarrhea, arthralgias, cough, fatigue, abdominal pain, and back pain. However, the incidence is no more frequent with ezetimibe than with placebo. Elevations in serum transaminases have also been reported. When used as monotherapy, the incidence of consecutive elevations (≥3 times the ULN) in serum transaminases is similar between ezetimibe (0.5%) and placebo (0.3%); however, when combined with a statin, the incidence of consecutive elevations in serum transaminases is 1.3% and only 0.4% in patients taking a statin alone. These elevations are usually transient and return to baseline after discontinuation. Although very rare, cases of myopathy and rhabdomyolysis have been reported with ezetimibe monotherapy.

PLACE IN THERAPY

Ezetimibe may be used alone or in combination with a statin or fenofibrate along with diet for the management of dyslipidemia, specifically to lower LDL-C. Ezetimibe reduces LDL-C by 18% to 22%, but has little effect on TG or HDL-C.[127] In combination with a statin, it demonstrates an additive effect, enhancing LDL-C lowering by an additional 10% to 20%. In fact, when added to a low dose of a statin, the net LDL-C reduction can be similar to the lowering achieved with the maximal dose of the statin.[128] When added to the maximal dose of a statin, it causes further LDL-C reduction, an effect important in patients with very high LDL-C levels requiring substantial reduction to achieve treatment goals.

DRUG INTERACTIONS

Ezetimibe has been evaluated in combination with several other medications. When combined with statins or fenofibrate there is minimal impact on either drug in terms of an alteration in metabolism and increased bioavailability that requires any additional intervention.[120] Post-marketing data have shown that there are some elevations in the international normalized ratio (INR) when ezetimibe is added to warfarin. The exact mechanism of this interaction is not fully understood and no specific dose adjustments are necessary for either medication. However, when ezetimibe is initiated in a patient on warfarin, closer monitoring of the INR may be warranted. Cyclosporine in combination with ezetimibe results in increased exposure of both medications. When used in combination, serum concentrations of cyclosporine should be closely monitored and adjusted as clinically indicated. Additionally, the recommended initial dose of ezetimibe when used in combination with cyclosporine is 5 mg daily.

When cholestyramine or colestipol are in combination with ezetimibe there is an 80% reduction in the area under the curve of ezetimibe. Therefore, when these combinations are used ezetimibe should be administered at least 2 hours prior or 4 ounces following the administration of cholestyramine or colestipol.[120] The absorption of ezetimibe is not affected by colesevelam and this combination may be preferred.

CLINICAL PEARLS

Adding ezetimibe to a statin results in greater LDL-C reduction than increasing the dose of the statin. Doubling the dose of any statin provides only an additional 6% reduction in LDL-C. The addition of ezetimibe to statin therapy results in an approximate 18% additional reduction in LDL-C. However, maximally tolerated statin therapy is always recommended prior to consideration of the addition of non-statin therapy.

Due to a risk of increased hepatic serum transaminases, these laboratory values should be measured prior to the addition of ezetimibe to statin therapy and again following 6 weeks of combination therapy.

Ezetimibe monotherapy or combination therapy with statin should be avoided in patients with active liver disease or persistent elevations in serum transaminases that are otherwise unexplained.

Niacin

On the basis of currently available evidence of nonefficacy and potential harms, there are no clear indications for the routine use of niacin preparations and niacin is, therefore, not considered in this discussion.

CASE 8-5

QUESTION 1: RP is a 62-year-old male, with history of CHD (bypass 2 years ago), diabetes, end-stage renal disease (ESRD) on hemodialysis Monday, Wednesday, and Friday. He is on lisinopril 10 mg daily, atorvastatin 40 mg daily, aspirin 81, metoprolol succinate 50 mg daily, insulin, and calcium acetate 667 mg 3 times daily. His BP is 136/82 mm Hg; HgA$_{1c}$ 11.6%; Wt 132 kg; Ht 5′10″; fasting lipid panel TC = 250 mg/dL, HDL-C = 30 mg/dL, TG = 450 mg/dL.

What would be the most appropriate treatment for RP and his dyslipidemia?

While RP does have elevated TGs, per the Endocrinology and AHA guidelines, pharmacologic therapy is not indicated at this time. The most important intervention for RP is lifestyle modifications. Controlling his diabetes and losing weight can successfully lower his TGs as much if not more than pharmacologic therapy.

CASE 8-5, QUESTION 2: If pharmacologic therapy were initiated on RP for his hypertriglyceridemia, which agent(s) would be the most appropriate?

All fibric acid derivatives undergo renal elimination and none of these agents are approved for patients on hemodialysis and are therefore not a good option in RP. Omega-3 fatty acids would be the best option to use in combination with atorvastatin that he is already taking.

Fibric Acid Derivatives

MECHANISM OF ACTION

Fibrates activate peroxisome proliferator-activated receptors α (PPARα) causing most of the beneficial effects on blood lipids.[129] PPARα are located in the nucleus of cells and are ligand-dependent transcription factors that regulate target gene expression. Stimulation of PPARα suppresses the gene responsible for the synthesis of apo C-III and stimulates the gene responsible for LDL receptor synthesis.[129,130] As a result, lipolysis of TGs from VLDL particles and the removal of these particles via hepatic LDL receptors are enhanced. Stimulation of PPARα also increases fatty acid oxidation, reducing the synthesis of TGs in the liver, reducing the TG content of secreted VLDL particles.[130] Stimulation of PPARα may increase the synthesis of apo A-I, the critical building block of nascent HDL, thereby enhancing reverse cholesterol transport. Research also suggests that fibrates stimulate the expression of ABCA-1 transporters in macrophage cells, which are responsible for bringing cholesterol from within the cell to the cell surface, where it can be taken up by nascent HDL particles and removed from the cell[129] (Fig. 8-13).

EFFICACY

The results of three major primary prevention trials have raised questions about the safety of fibrates. In the World Health Organization trial, clofibrate reduced nonfatal MI by 25%, but caused an increase in total mortality.[131,132] As a result, its use has declined markedly in the United States. Some of these deaths may have been related to gallstone disease.[131] In the Helsinki Heart Study (HHS), gemfibrozil reduced fatal and nonfatal MI by 37%, but was associated with a slight increase in non-CHD mortality such that there was no net reduction in total mortality.[133] Follow-up evaluations of therapies without gemfibrozil were associated with continued event reduction. In the Veterans Affairs High Density Lipoprotein Intervention (VA-HIT) trial, there was a significant 22% relative risk reduction in death from CHD with gemfibrozil ($p < 0.006$). There was also a 24% reduction in the combined endpoint of death from coronary revascularization, hospitalization due to angina, nonfatal MI, and stroke ($p < 0.001$). However, there was no significant effect on mortality.[134] In the Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) study, fenofibrate did not significantly reduce CHD deaths and nonfatal MI compared with placebo. In addition, more patients receiving fenofibrate had pancreatitis or a pulmonary embolism compared with those given placebo.[135] Fenofibrate was also evaluated versus placebo in 418 patients with diabetes and at least one visible lesion on angiographic evaluation in the Diabetes Atherosclerosis Intervention Study (DAIS) trial.[136] The trial was not powered to examine clinical endpoints, but fewer events, including deaths, occurred in the fenofibrate group. In summary, the clinical trial evidence for cardiovascular benefit of the fibric acid derivatives is not as robust as for the statins. The data supporting the use of gemfibrozil in the primary and secondary prevention setting have been established. In contrast, clear improvements in CHD-related outcomes are still lacking for fenofibrate. Thus, these data support the use of fibric acid derivatives as second-line agents, with the exception of use in patients with severe hypertriglyceridemia. More recently, the incremental benefits of adding fenofibrate to background simvastatin therapy on CHD events in patients with diabetes were reported. Only patients with the highest tertile ($\geq$204 mg/dL) of TGs and the lowest tertile ($\leq$34 mg/dL) of HDL-C showed a benefit when fenofibrate was added to statin therapy. Overall, there was an insignificant 8% reduction in the composite cardiovascular endpoint, and fenofibrate appeared to be harmful in women compared with men.[137]

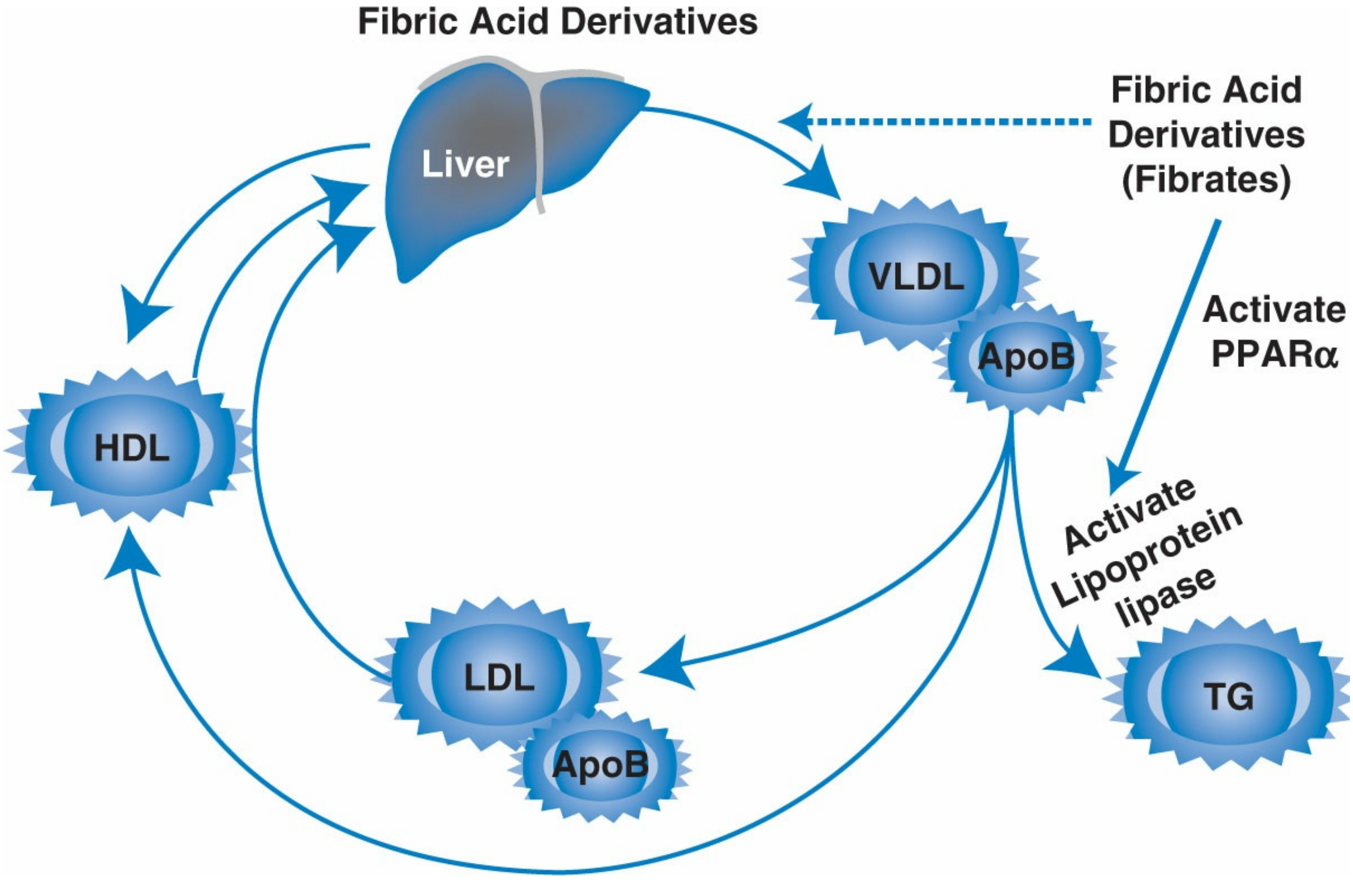

Figure 8-13 Mechanism of action of fibric acid derivatives. apo B, apolipoprotein B; HDL, high-density lipoprotein; LDL, low-density lipoprotein; PPAR-**a**, peroxisome proliferator-activated receptor alpha; TG, triglycerides.

PHARMACOKINETICS/PHARMACODYNAMICS

Fenofibrate and fenofibric acids are well absorbed from the GI tract.[138–145] Fenofibrate is primarily metabolized by conjugation with peak plasma concentrations within 6 to 8 hours after administration. It is highly bound to plasma proteins, with an elimination half-life of 20 hours. The primary route of excretion is via the urine in the form of metabolites.

On the other hand, gemfibrozil is completely absorbed following administration and reaches peak plasma concentrations within 1 to 2 hours.[146] The rate and extent of absorption is optimal when taken 30 minutes prior to meals as food can result in a 14% to 44% reduction in the area under the curve. It is highly bound to plasma proteins, with an elimination half-life of 1.5 hours. It undergoes extensive hepatic metabolism via oxidation of the ring methyl group to form carboxyl and hydroxymethyl metabolites. Gemfibrozil relies significantly on renal excretion with approximately 70% being eliminated by the kidneys as a glucuronide conjugate.[146]

Dosing of fibric acid derivatives in patients with renal insufficiency is outlined in Table 8-10.

ADVERSE EFFECTS

Gemfibrozil, fenofibric acid, and fenofibrate are usually well tolerated. The most common adverse effects associated with fibric acid derivatives include, nausea, vomiting, dyspepsia, diarrhea, abdominal pain, flatulence, and constipation. Gemfibrozil causes mild GI symptoms (nausea, dyspepsia, abdominal pain) in about one-third of patients. Fenofibrate causes a rash in 2% to 4% of patients. Fibrate therapy can also cause muscle side effects, including myositis and rhabdomyolysis.[138–143] Most cases of muscle toxicity have been reported with gemfibrozil, especially when it is used in combination with a statin. Recent studies reveal that the area under the blood concentration curve of most statins is increased twofold to fourfold when given concurrently with gemfibrozil. These effects have not been observed with fenofibrate. The mechanism causing this interaction appears to be related to inhibition of glucuronidation by gemfibrozil, which is a metabolic pathway for statins, thereby reducing clearance of statins from the systemic circulation.[147]

Fibric acid derivatives have also been associated with abnormalities in liver function tests including bilirubin and alkaline phosphatase.[138–146] However, these elevations are often not worrisome and usually return to baseline levels upon discontinuation. Fenofibrate has been shown to cause a reversible increase in serum creatinine.[138–145] Although also observed with gemfibrozil, the incidence is lower. Despite this increase, there does not appear to be a resultant decrease in GFR and the mechanism for this effect has not been clearly defined. Gemfibrozil also increases biliary secretion of cholesterol, which increases the lithogenicity of bile and results in the development of cholesterol gallstones. Presumably, the same effect occurs with all fibrates.

PLACE IN THERAPY

Gemfibrozil, fenofibric acid, and fenofibrate are all indicated for the reduction of TG levels in patients with hypertriglyceridemia.[138–146] The NLA recommends a fibric acid derivative as one of several agents that may be initiated in patients who have TG levels > 1,000 mg/dL and are at risk for experiencing pancreatitis.[7] The AHA/ACC define hypertriglyceridemia at a TG level >500 mg/dL and make no formal recommendations on the use of fibric acid derivatives in this setting.[5] Similarly, in patients with familial dysbetalipoproteinemia, fibric acid derivatives are highly effective and are considered the drugs of choice. Fibrates also have a place in the management of combined or mixed hyperlipidemia. Support for this comes primarily from the results of the HHS and the VA-HIT trials, in which gemfibrozil combined with diet therapy was associated with a reduction in CHD deaths and nonfatal MI.[133,134] These positive outcomes are attributed to significant reductions in serum TGs (and, therefore, a reduction in TG-rich VLDL remnants and in small, dense LDL) and an increase in HDL-C. Persons most likely to benefit are those with diabetes or the lipid triad found in patients with the metabolic syndrome.

Table 8-10

Dosing of Fibric Acid and Fenofibric Acid Derivatives in Renal Insufficiency

Medication	**Usual Dose**	**Creatinine Clearance 30–59 mL/minute**	**Creatinine Clearance 31–80 mL/minute**	**Creatinine Clearance Ä30 mL/minute or Hemodialysis**
Gemfibrozil	600 mg twice daily		No specific recommendations	Not recommended
Fenofibrate (Fenoglide)	40–120 mg daily		Start at lowest dose of 40 mg daily	Contraindicated
Fenofibrate (Tricor)	48–145 mg daily	Start at lowest dose of 48 mg		Contraindicated
Fenofibrate (Fibricor)	35–105 mg daily		Start at lowest dose of 35 mg	Contraindicated
Fenofibrate (Liopfen)[a]	50–150 mg daily		Start at lowest dose of 50 mg daily	Contraindicated
Fenofibrate (Antara)	43–130 mg daily		Start at lowest dose of 43 mg daily	Contraindicated
Fenofibrate (Lofibra tablets)	54–160 mg daily		Start at lowest dose of 54 mg	Contraindicated
Fenofibrate (Lofibra micronized)	67–200 mg daily		Start at lowest dose of 67 mg	Contraindicated
Fenofibrate (Triglide)	160 mg daily		Avoid use	Contraindicated
Fenofibrate (Trilipix)	45–135 mg daily	Start at lowest dose of 45 mg		Contraindicated

[a] CrCl is 30–89 mL/minute.

DRUG INTERACTIONS

Drug interactions associated with fibric acid derivatives are fairly well known and several of these drug interactions can be managed by careful monitoring. The most clinically significant interactions occur with statins, warfarin, repaglinide, cholestyramine, and colestipol. The combination of statins and gemfibrozil increases systemic concentrations of the statin and raises the risk for the development of myopathy and rhabdomyolysis. As previously mentioned, data suggest that there is less risk of a significant drug interaction with fenofibrate, and subsequently a lower risk of myopathy and rhabdomyolysis. The combination of gemfibrozil should be avoided with lovastatin, pravastatin, and simvastatin. The maximum dose of rosuvastatin should be 10 mg daily when combined with gemfibrozil. Although gemfibrozil does interact with atorvastatin and pitavastatin, the increase in statin concentrations is minor and the combination may be utilized if clinically indicated. However, there are no data demonstrating that adding a fibrate to a statin will reduce CHD risk. The co-administration of gemfibrozil with ezetimibe may cause increased cholesterol excretion into the bile, increasing the risk of cholelithiasis.[120,146] This does not appear to be a concern with fenofibrate and ezetimibe combination.

CASE 8-6

QUESTION 1: J.S. is a 46-year-old male with a history of hypertension and diabetes. He presented to his primary care physician with a chief complaint of abdominal pain that began 2 days ago and radiated to his mid-back. He also has some vomiting. All of his vital signs were within normal limits. On physical exam he has tenderness over his abdominal area that is more severe in the epigastric region. Pertinent laboratory values include an HgA_{1c} of 13.6% and the following cholesterol panel: total cholesterol 467 mg/dL, HDL-C 30 mg/dL, TG 1,872 mg/dL, LDL-C was unable to be calculated, amylase 325 U/L, and lipase 3,265 U/L.

Following acute management of his pancreatitis, what would be the most appropriate treatment for J.S.?

This is an individual that is high risk for pancreatitis as well as ASCVD. His risk score using the new risk calculator based on recent guidelines reveals a 10-year risk of about 18.6% and a statin is indicated. Additionally, the endocrinology guidelines define a triglyceride level of ≥1,000 mg/dL as severe and the AHA guidelines define a level ≥500 mg/dL as very high and that pharmacologic therapy should be initiated. J.S. should be initiated on a statin and a fibric acid derivative, or two different agents to lower TGs first such as omega-3 fatty acids plus fibric acid derivative to get TGs down and then consider the addition of a statin.

CASE 8-6, QUESTION 2: What are some considerations when using fibric acid derivatives in combination with statins?

The risk of adverse effects of statin–fibrate combination therapy is dependent on pharmacokinetic interactions that alter statin metabolism and clearance. One of the most significant drug interactions with statins and a fibric acid derivative is the combination of a statin with gemfibrozil. Gemfibrozil inhibits glucuronidation which is an elimination pathway of all statins with the exception of fluvastatin. This interaction can lead to increased concentrations of these statins, increasing the risk of toxicity. In contrast, fenofibrate appears to have a minimal effect and is considered a safer alternative. The use of gemfibrozil with simvastatin, pravastatin, or lovastatin should be avoided. The combination gemfibrozil with atorvastatin, pitavastatin, and rosuvastatin may be considered if fenofibrate is not an option.[118] However, lower doses of statins should be used to minimize adverse effects. Labeling for rosuvastatin suggests limiting the daily dose of rosuvastatin to 10 mg daily when used with gemfibrozil.

CLINICAL PEARLS

Many different formulations of fenofibrate are available with the dose ranging from 130 to 200 mg. All products are dosed once daily. For the treatment of hypertriglyceridemia, the initial dose may be at the lower end of the dosing range. If the initial dose chosen is lower than the maximum dose, it should be titrated upwards at 4- to 8-week intervals based on patient response up to the maximum dose.

Obtain a baseline serum creatinine prior to the initiation of therapy.
Gemfibrozil is preferred in renal insufficiency.
Consider discontinuation of fibric acid derivative or a dose reduction in the setting of otherwise unexplained increases in serum creatinine.
Fenofibrate is the preferred agent to use when combination with a statin is warranted.
Obtain a baseline CK prior to adding a fibrate to statin therapy and in those patients at high risk.

Patients who receive any fibric acid derivative therapy alone or in combination with a statin should be monitored for symptoms of muscle soreness and pain. If these symptoms emerge, a CK level should be obtained. CK level ≥10 times the ULN in combination with muscle symptoms supports a diagnosis of myositis. If other possible causes are not apparent, such as increased physical exercise or a recent trauma or fall, the presence of myositis is an indication to withdraw fibrate therapy.

Omega-3 Fatty Acids

MECHANISM OF ACTION

The exact mechanism by which the omega-3 fatty acids, dicosohexanoic acid (DHA) and eicosopentanoic acid (EPA), lower TGs is not fully understood. There are currently three prescription fish oil formulations available: combined EPA and DHA in ethyl ester form, EPA ethyl ester only, and EPA and DHA in carboxylic acid form.[148–150] The ethyl ester formulation may possibly work thru inhibition of acyl CoA:1,2-diacylglycerol acyltransferase and increased peroxisomal B oxidation. However, DHA and EPA inhibit the esterification of other fatty acids, and triglyceride lowering may be due to a reduction in hepatic TG synthesis.[148] The active metabolite of icosapent ethyl ester reduces hepatic VLDL-TG synthesis and/or secretion and increases TG clearance from circulating VLDL particles.[149] The potential mechanisms of action for the carboxylic acid formulation include inhibition of acyl-CoA:1,2-diacylglycerol acyltransferase, increased mitochondrial and peroxisomal oxidation in the liver, decreased lipogenesis in the liver, and increased plasma lipoprotein lipase activity. This agent may reduce the synthesis of TGs in the liver.[149]

EFFICACY

Consumption of foods rich in omega-3 fatty acids (e.g., fish) several times a week has been associated with a reduced risk of heart disease and is recommended as part of a low-fat diet. Supplements of fish oils demonstrated a reduction in CHD in patients with a recent MI[151] as well as patients taking statins.[152] Recently, however, other trials have failed to demonstrate the benefits of omega-3 fatty acids in addition to standard cardiovascular drugs, such as statins, angiotensin-converting enzyme (ACE) inhibitors, β-blockers, and antiplatelet agents.[153] Commercial sources of fish oils vary in their content. The omega-3 fatty acids used in the GISSI study, which demonstrated a CHD risk reduction, contained 850 mg of combined EPA and DHA. Currently two trials, the Reduction of Cardiovascular Events with EPA-Intervention trial (REDUCE-IT) and Outcome Study to Assess Statin Residual Risk Reduction with Epanova in Hypertriglyceridemia (STRENGTH), are underway to evaluate cardiovascular outcomes in patients with CHD or at high risk for CHD (REDUCE-IT) or high risk for CHD (STRENGTH) already taking statin therapy. The results of these trials will help to carve out the role of these agents in this patient population.[154,155]

PHARMACOKINETICS/PHARMACODYNAMICS

There is limited pharmacokinetic or pharmacodynamic data available for these agents. The combined EPA and DHA ethyl ester formulation (Lovaza ^{R}, Omtryg^{R}) is well absorbed following oral administration. The EPA and DHA carboxylic acid preparation (Epanova^{R}) is directly absorbed in the small intestines subsequently entering the systemic circulation mainly via the thoracic duct lymphatic system.[150] Steady-state concentrations of EPA and DHA in plasma are achieved within 2 weeks following repeat daily dosing. The omega-3 fatty acids in carboxylic acid form may be administered without regard to meals. They are mainly oxidized in the liver and do not undergo renal elimination.

Following oral administration, the EPA ethyl ester preparation (Vasepa ^{R}) is de-esterified during process and the active metabolite EPA is absorbed in the small intestine and enters the systemic circulation mainly via the thoracic duct lymphatic system.[149] Peak plasma concentrations of EPA are reached in approximately 5 hours. No studies on the effect of food on this product have been conducted. However, the recommendation is for it to be taken with or following a meal. The EPA ethyl ester is mainly metabolized by the liver via β-oxidation. This beta oxidation splits the long carbon chain of EPA into acetyl coenzyme A which is then converted into energy via the Krebs cycle. EPA ethyl ester does not undergo renal elimination.

ADVERSE EFFECTS

The most common adverse effects associated with Lovaza are eructation, dyspepsia, and taste perversion. In addition to eructation, Epanova has also been reported to cause diarrhea, nausea, and abdominal pain. The most common adverse effect reported with Vasepa is arthralgia.

PLACE IN THERAPY

Fish oils predominantly contain long-chain polyunsaturated (omega-3) fatty acids, EPA and DHA, which lower TG levels significantly (30%–60%) but have variable effects on cholesterol levels. They do not provide LDL-C reduction. All of the available prescription products may be used as an adjunct to diet to treat hypertriglyceridemia. The recommended dose of Lovaza is 4 g/day in either a single or divided dose. The dose for Vasepa is 2 g twice daily with food and Epanova is 2 to 4 g daily.

DRUG INTERACTIONS

No significant drug interactions have been reported with any of the prescription products. However, some studies suggest that the use of omega-3 fatty acids may prolong bleeding time. However, there have been no thorough clinical trials conducted to determine the magnitude of this interaction. Therefore, patients taking these along with other anticoagulants should be evaluated more closely for any signs of increased bleeding.

CLINICAL PEARLS

Omega-3 fatty acid capsules should be swallowed whole. Do not break open, crush, dissolve, or chew.

Administering fish oil before meals may decrease the fishy taste.

EPA has negligible effect on LDL-C Both EPA and DHA lower triglycerides but DHA as well as the combination of EPA/DHA is more effective than EPA-only preparations DHA-containing preparations may increase LDL-C, mechanism likely due to increase in apoC-III production.

Bile Acid Resins

MECHANISM OF ACTION

Bile acids are secreted into the intestines and are responsible for emulsifying fat and lipid particles in food. Most of the bile acids that are secreted are reabsorbed and returned to the liver by enterohepatic circulation. The BASs are anion-exchange resins that bind bile acids in the intestinal lumen and cause them to be eliminated in the stool.[156–159] By disrupting the normal enterohepatic recirculation of bile acids from the intestinal lumen to the liver, the liver is stimulated to convert hepatocellular cholesterol into bile acids. This results in a reduction in the concentration of cholesterol in the hepatocyte, prompting upregulation of LDL receptor synthesis. Finally, circulating LDL-C levels are lowered by binding to the newly formed LDL receptors on the liver surface (Fig. 8-14).

EFFICACY

The BAS agents have demonstrated the ability to reduce CHD events in the Lipid Research Clinics Coronary Primary Prevention Trial (LRC-CCPT).[160] This was a randomized, multicenter trial evaluating the efficacy of cholesterol lowering in reducing coronary artery disease (CAD) risk in 3,806 men with primary hypercholesterolemia. In conjunction with diet, patients were randomized to cholestyramine 24 g/day or placebo. The mean follow-up was 7.4 years. The primary endpoint of combined CAD death and non-fatal MI was reduced by 19% in the patients treated with cholestyramine compared to placebo-treated patients ($p < 0.05$). This study also supports the "lower is better" hypothesis of LDL-C.[160,161] These agents reduce LDL-C between 12% and 27%, total cholesterol by 8% and 27%. HDL-C is increased minimally by around 3% to 10%. All of the BAS also may raise TG levels by 3% to 10% or more, especially in patients with high TG levels.

PHARMACOKINETICS/PHARMACODYNAMICS

Colesevelam is a nonabsorbable polymeric compound that binds to bile acids more strongly and more specifically than the other available BAS.[159] Colestipol and cholestyramine are nonabsorbable hydrophilic basic anion exchange resins. All of these agents are insoluble in water.[157,158]

ADVERSE EFFECTS

The most common adverse effect associated with these agents is constipation. Additional adverse effects include abdominal bloating, epigastric fullness, nausea, vomiting, steatorrhea, and flatulence.[157–160] The incidence of these GI symptoms is less with colesevelam.

PLACE IN THERAPY

BAS are indicated as an adjunct to diet and exercise to lower LDL-C. These agents may be used alone or in combination with statins. The BAS have appeal in the management of hypercholesterolemia because they have a strong safety record and they effectively lower LDL-C. They are not absorbed from the gastrointestinal (GI) tract and thus lack systemic toxicity. Older BAS (cholestyramine, colestipol) are not well tolerated due to numerous GI side effects and the unpleasant granular texture of the powder. Therefore, colesevelam is currently the preferred agent. Colesevelam is indicated as monotherapy or in combination with a statin to reduce LDL-C levels in boys and postmenarchal girls, 10 to 17 years of age, with HeFH. Therapy may be initiated following adequate trial of diet if LDL-C remains ≥190 mg/dL or LDL-C remains ≥160 mg/dL and there is a positive family history of premature ASVD or two or more other CVD risk factors. Colesevelam is also approved by the US FDA for use in type 2 diabetes to improve glycemic control.[159]

DRUG INTERACTIONS

Reduction in the absorption of fat-soluble vitamins and folic acid has been reported with high dosages of BAS, but this is rarely a problem in otherwise healthy patients consuming a nutritionally balanced diet. Cholestyramine and colestipol may reduce or delay the absorption of medications when co-administered.[157–159] This can be minimized by administering other medications 1 hour before or 4 hours after the resin dose. The resins may also reduce the absorption of warfarin, levothyroxine, thiazide diuretics, β-blockers, and presumably other anionic drugs. Colesevelam has been shown to reduce levels of glimepiride, glipizide, glyburide, levothyroxine, cyclosporine, olmesartan, and oral contraceptives containing esthynyl estradiol and norethindrone. To avoid these interactions, these agents should be administered 4 hours prior to colesevelam. Colesevelam has also been shown to increase metformin levels and patients should be monitored for clinical response. Post marketing reports have also shown an interaction with phenytoin. As with the other drug interactions, phenytoin should be administered 4 hours prior to colesevelam.

CLINICAL PEARLS

Use of BAS should be avoided in patients with complete biliary obstruction.

BAS are contraindicated if TGs are >500 mg/dL and in patients with a history of hypertriglyceridemia-induced pancreatitis.

Colesevelam for oral suspension should be mixed with 4 to 8 ounces of water, fruit juice, or diet soft drinks.

These agents should be initiated only when TG levels are <300 mg/dL.

Microsomal Triglyceride Protein Inhibitors (Lomitapide)

MECHANISM OF ACTION

Lomitapide is the first in a new class of antihyperlipidemic agents to improve lipoprotein profiles in patients with HoFH. Microsomal triglyceride protein (MTP) resides in the lumen of the endoplasmic reticulum. Inhibiting MTP production prevents the assembly of apoB-containing lipoproteins in enterocytes and hepatocytes. This subsequently inhibits the production and subsequent secretion of chylomicrons and VLDL, and subsequent production of LDL-C.[162]

EFFICACY

There is one pivotal phase III study that ultimately led to the approval of lomitapide. This was a multinational, single-arm, open-label, 78-week trial in 29 patients with HoFH.[163] Following a 6-week run in phase, patients were initiated on lomitapide 5 mg daily and titrated to doses of 10, 20, 40 mg, up to 60 mg, based on tolerability and liver enzymes levels.[163] Patients were also instructed to follow a low-fat diet (<20% of calories from fat) as well as to take dietary supplements to replace fat-soluble nutrients.

Initial efficacy was assessed after 26 weeks and then patients were continued on the study medication for an additional 52 weeks to assess for long-term safety. The primary endpoint was change in LDL-C from baseline at 26 weeks. The results showed that lomitapide, when added to the existing lipid-lowering therapy, significantly reduced LDL-C by an average of 40% from baseline at week 26.[163]

PHARMACOKINETICS/PHARMACODYNAMICS

Lomitapide undergoes extensive hepatic metabolism. Metabolic pathways include oxidative-N-dealkylation, glucuronide conjugation, oxidation, and piperidine ring opening. The CYP3A4 isoenzyme metabolizes lomitapide to its major metabolites. Lomitapide is highly bound to plasma proteins (99.8%) and has a mean terminal elimination half-life of 39.7 hours. Approximately 59.5% and 33.4% of the dose is excreted in the urine and feces, respectively.[162]

PLACE IN THERAPY

Lomitapide is approved as an adjunct to a low-fat diet and other lipid-lowering therapies, including LDL apheresis, to reduce LDL-C, TC, apo B, and non–HDL-C in patients with HoFH. Due to the concern for liver injury the drug is only available thru a Risk Evaluation and Mitigation Strategies (REMS) program. Given the risk of adverse effects, unknown effects on cardiovascular morbidity and mortality, as well as the absence of data in the non-HoFH population, lomitapide treatment should be restricted to patients with HoFH.

ADVERSE EFFECTS

The primary adverse effects associated with lomitapide include GI symptoms, elevated transaminases, and hepatic steatosis. The

---

most common GI symptom report was diarrhea which occurred in 79% of patients, followed by nausea (65%), dyspepsia (38%), and vomiting (34%). Additional GI symptoms that have been reported include abdominal pain and discomfort, constipation, and flatulence. To minimize the risk of these adverse effects, patients should adhere to a diet that is low in fat (<20% of daily energy). Elevations in hepatic transaminases occurred in 34% of patients. The degree of elevation ranged from an ALT or AST of ≥3× the ULN to 5× the ULN. However, no patients in the clinical trial had to discontinue therapy due to elevated transaminases.

DRUG INTERACTIONS

The use of lomitapide in combination with strong inhibitors of CYP3A4 (boceprevir, clarithromycin, conivaptan, indivavir, itraconazole, ketoconazole, lopinavir/ritonavir, mibefradil, nefazodone, nelfinavir, posaconazole, ritonavir, saquinavir, telaprevir, voriconazole, telithromycin), moderate inhibitors of CYP3A4 (amprenavir, aprepitant, erythromycin, fluconazole, fosamprenavir, imatinib, verapamil, crizotinib, atazanavir, diltiazem, darunavir/ritonavir) as well as grapefruit juice is contraindicated. Strong CYP3A4 inhibitors in combination with lomitapide can result in an approximately 27-fold increase in exposure of lomitapide. Moderate CYP3A4 inhibitors in combination with lomitapide have not been fully evaluated but are expected to increase lomitapide levels. Even weak CYP3A4 inhibitors can increase lomitapide exposure by approximately twofold. When lomitapide is used in combination with warfarin, the INR may increase by as much as 22%. Lomitapide in combination with simvastatin leads to doubling of simvastatin exposure. When used in combination with statin therapy, the dose of statin should be reduced by 50% and the dose of simvastatin should be limited to 20 mg daily. A dose of simvastatin of 40 mg daily may be used if patients have previously tolerated simvastatin for at least a year at a dose of 80 mg daily. While specific drug interactions between lomitapide and lovastatin have not been studied, given that the metabolizing enzymes and transporters responsible for the disposition of these two agents are similar, a reduced dose of lovastatin should be considered. Lomitapide is also an inhibitor of P-glycoprotein (P-gp). The use of lomitapide in combination with P-gp substrates (aliskiren, fexofenadine, topotecan, sitagliptin, saxagliptin, imatinib, maraviroc, digoxin, dabigatran, ambrisentan, colchicine, everolimus, lapatinib, nilotinib, posaconazole, sirolimus, talinolol, tolvaptan, sirolimus, tolvaptan, talinolol) may lead to increased absorption of these agents and dose reduction should be considered. Although not tested, it is recommended that BAS be administered at least 4 hours apart from lomitapide. This is to avoid potential interference with absorption of lomitapide.[160]

CLINICAL PEARLS

The initial dose of lomitapide is 5 mg once daily with a full glass of water, and at least 2 hours following the evening meal.

Patients should adhere to a low-fat diet consisting of <20% of their dietary intake when prescribed lomitapide.

Patients should also consume supplements (provided by pharmacy with lomitapide prescription) that contain vitamin E (400 IU), linoleic acid (200 mg), alpha-linolenic acid (210 mg), EPA (110 mg), and DHA (80 mg).

The dose of lomitapide can be increased after 2 weeks to 10 mg once daily and then titrated upwards as follows: at 6 weeks increase the dose to 20 mg once daily, at 10 weeks increase to 40 mg once daily, and after 14 weeks the dose may be increased to the maximum dose of 60 mg.

The maximum dose in patients with ESRD on hemodialysis or mild hepatic impairment is 40 mg once daily.

The use of lomitapide is contraindicated in patients with active liver disease (unexplained persistent elevations of serum transaminases), moderate to severe hepatic impairment, pregnancy, as well in combination with moderate or strong CYP3A4 inhibitors as outlined above.

Patients on warfarin along with lomitapide should have their INR closely monitored and warfarin dosage adjusted as needed.

Obtain ALT, AST, and total bilirubin prior to initiation of therapy, prior to each dose increase, or monthly, whichever comes first.

After the first year of therapy, ALT, AST, and total bilirubin should be monitored at least every 3 months and prior to any dose increase. If the LFTs are >3× the ULN and <5× the ULN, repeat labs in 1 week to confirm the elevation. If the elevation is confirmed, reduce the dose and obtain additional liver-related tests. Repeat labs weekly and discontinue therapy if LFTs increase >5× the ULN and do not decrease to <3× the ULN within approximately 4 weeks.

Apo B Antisense Oligonucleotides

MECHANISM OF ACTION

Mipomersen is an antisense oligonucleotide targeted to human messenger ribonucleic acid (mRNA) for apo B-100. Mipomersen is complementary to the coding region of the mRNA for apo B-100 and binds by Watson and Crick (guanine–cytosine and adenine–thymine) base pairing. The hybridization of this agent to the cognate mRNA results in RNase H-mediated degradation of the cognate mRNA thereby inhibiting translation of the apo B-100 protein. This action leads to reduced apo B synthesis, the structural core for all atherogenic lipids, including LDL-C.[164–166]

EFFICACY

Mipomersen has been evaluated in two phase III studies. The first was a randomized, double-blind, placebo-controlled multicenter trial in 58 patients with FH. Patients were included if their LDL-C was ≥140 mg/dL or LDL-C ≥92 mg/dL plus CAD, on maximally tolerated lipid-lowering therapy. Patients were administered subcutaneous dose of 200 mg of mipomersen weekly for 26 weeks or placebo.[167] The results showed a 36% reduction in LDL-C versus a 13% increase with placebo ($p < 0.001$). Additionally, apo B and lipoprotein(a) were also significantly reduced ($p < 0.001$). ALT and AST were increased in 21% and 13% of patients, respectively. Hepatic steatosis was observed with an incidence of 13%. The second phase III study was also a randomized, double-blind, multicenter study evaluating 158 patients with baseline LDL-C ≥100 mg/dL with or at high risk for CAD and on maximum tolerated lipid-lowering therapy.[168] As with the previous study, mipomersen 200 mg was administered subcutaneously once a week for 26 weeks. The results revealed a 36.9% reduction in LDL-C compared to a 4.5% reduction with placebo ($p < 0.001$). Apo B was significantly reduced by 38% as was lipoprotein(a) by 24% ($p < 0.001$). Additionally, half of the patients achieved LDL-C levels of <70 mg/dL in the mipomersen group. Elevations in ALTs observed were similar to other studies and ALT > 3× the ULN occurred in 10% of patients.

PHARMACOKINETICS/PHARMACODYNAMICS

Mipomersen is administered via subcutaneous injection. The drug has a bioavailability ranging from 54% to 78%. Peak plasma concentrations are generally obtained within 3 to 4 hours. With weekly administration, steady state is reached within approximately 6 months. It is highly bound to human plasma (≥90%) and has an elimination half-life of 1 to 2 months following subcutaneous administration. Mipomersen is metabolized in tissues by endonucleases to form shorter oligonucleotides that are then substrates for additional metabolism by exonucleases. Mipomersen is not a substrate for the CYP450 enzyme system. Elimination occurs via metabolism in the tissues and urinary excretion.[164]

ADVERSE EFFECTS

The most common adverse effects associated with mipomersen with an incidence of ≥10% include injection site reactions, flu-like symptoms, nausea, headache, and elevated hepatic transaminases, specifically ALT. Injection site reactions occur in 84% of patients and consist of pain, tenderness, erythema, pruritus, and local swelling. Flu-like symptoms occur in 30% of patients and are usually noticed within 2 days after the injection. These symptoms include pyrexia, myalgia, chills, arthralgia, fatigue, and malaise. Elevations in hepatic transaminases occurred in approximately 12% of patients, with 9% having an ALT ≥ 3× the ULN. Hepatic steatosis has also been reported.

PLACE IN THERAPY

Mipomersen is indicated as an adjunct therapy to a low-fat diet and other lipid-lowering agents to reduce LDL-C, ApoB, TC, and non-HDL in patients with HoFH.[164] Due to concern for hepatotoxicity, mipomersen is also available only through a REMS program. Although mipomersen has only been studied in combination with simvastatin and ezetimibe therapies, its use with other non-statin lipid-lowering agents as well as in patients undergoing LDL-C apheresis is not recommended. The effect of mipomersen on cardiovascular morbidity and mortality is unknown. Additionally, the safety and efficacy of mipomersen has not been established in patients with hypercholesterolemia not secondary to HoFH. Maximum LDL-C reduction is usually seen after approximately 6 months of therapy.

DRUG INTERACTIONS

Secondary to the unique metabolism of mipomersen, there are no known clinically significant drug interactions. However, caution should be exercised when used with other medications known to have potential for hepatotoxicity, (e.g., isotretinoin, amiodarone, acetaminophen [>4 g/day for ≥3 days/week]), methotrexate, tetracyclines, and tamoxifen. If used in combination, more frequent monitoring of liver-related tests may be necessary.

CLINICAL PEARLS

Alcohol consumption should be limited to no more than 1 drink/day as it may increase hepatic fat and induce or exacerbate the risk of liver injury.

The recommended dose of mipomersen is 200 mg by subcutaneous injections once a week.

If a dose is missed, the injection should be given at least 3 days from when the next weekly dose is due.

Mipomersen should be stored in the refrigerator but removed from the refrigerator and allowed to reach room temperature for at least 30 minutes prior to administration.

Injection sites include the abdomen, thigh area, or outer area of upper arm.

Mipomersen should not be injected into any site that has injury to the skin such as sunburn, rash, skin infections, inflammation, or active areas of psoriasis, or in areas with tattoos or scars.

A full liver panel to include ALT, AST, total bilirubin, and alkaline phosphatase should be obtained prior to therapy initiation.

Mipomersen is contraindicated in patients with moderate or severe hepatic impairment or active liver disease.

For the first year, liver-related tests at least an ALT and AST should be checked monthly.

After the first year of therapy, liver tests should be checked at least every 3 months.

Discontinue therapy if persistent or clinically significant elevations occur.

If transaminase elevations are accompanied by clinical symptoms of liver injury, increases in bilirubin ≥2× the ULN, or active liver disease, therapy should be discontinued.

Lipid levels should be monitored at least every 3 months for the first year.

Proprotein Convertase Subtilisin/Kexin Type 9

MECHANISM OF ACTION

Proprotein Convertase Subtilisin/Kexin Type 9 (PCSK9) is a member of the proprotein convertase family, which consists of nine members. PCSK9 is thought to play a critical role in modulating the number of LDL receptors on the surface of the hepatocyte and consequently the amount of LDL-C in the plasma. PCKS9 binds irreversibly to LDL receptors on the hepatocyte and is internalized into the liver cells. This prevents the LDL receptor from being recycled back to the cell surface and the LDL-R/PCSK9 complex is degraded along with the LDL-C. Monoclonal antibodies to PCKS9, or PCSK9 inhibitors, neutralize PCSK9 and prevent PCSK9-mediated LDL receptor degradation, allowing more LDL receptors to return back to the cell surface. An increase in the number of LDL receptors leads to enhanced clearance of LDL-C and thus lower LDL-C levels (Fig. 8-15).[169,170]

EFFICACY

These agents have been evaluated in patients with HeFH and HoFH and in patients with ASCVD who have been on maximally tolerated statin doses and require further LDL-C reduction.

The LAPLACE-2 (LDL-C Assessment with PCSK9 Monoclonal Antibody Inhibition Combined with Statin Therapy) trial was a 12-week trial to evaluate the safety and efficacy of evolocumab in 2,067 patients with primary hypercholesterolemia and mixed dyslipidemia.[171] The study included 296 patients with clinical ASCVD. Patients were randomized to a specific, open-label regimen of three different statin doses (atorvastatin 80 mg daily, rosuvastatin 40 mg daily, or simvastatin 40 mg daily) and either fixed dose evolocumab 140 mg every 2 weeks, evolocumab 240 mg once a month, or placebo. The primary endpoint was change in baseline LDL-C at 12 weeks with a secondary endpoint of percent of patients achieving LDL-C of less than 70 mg/day. The results showed that in patients already on either moderate- or high-intensity statin therapy and clinical ASCVD, evolocumab demonstrated an additional mean reduction in LDL-C of 71% for the twice-weekly dose and 63% for the once-monthly dose compared to placebo ($p < 0.0001$). Additionally, 90% of evolocumab-treated patients achieved LDL-C < 70 mg/dL. The Durable Effect of PCSK9 Antibody Compared with Placebo Study (DESCARTES), was a randomized, double-blind, placebo-controlled 52-week trial comparing evolocumab versus placebo in 901 patients on background lipid-lowering therapy.[172] Background therapy included atorvastatin 80 mg with or without ezetimibe 10 mg daily. Of the entire study population, 139 patients had ASCVD. Evolocumab was administered 420 mg SQ once monthly. The results showed that in patients with ASCVD who received evolocumab, the mean percent LDL-C reduction was 54% ($p < 0.0001$). Alirocumab was evaluated in the COMBO study.[173] This was a multicenter, double-blind, placebo-controlled trial that randomly assigned patients to alirocumab or placebo in addition to maximally tolerated doses of statins with or without additional lipid-lowering therapy who required additional LDL-C lowering. The dose of alirocumab was 75 mg every 2 weeks. If additional LDL-C lowering was still needed at 12 weeks, the dose of alirocumab was increased to 150 mg every 2 weeks and continued for another 12 weeks. At 24 weeks, the mean reduction in LDL-C with alirocumab was 44% compared to 2% with placebo ($p < 0.0001$). A significant portion (84%) of the study population had ASCVD. After 12 weeks, the mean reduction in LDL-C from baseline was 45% versus 1% with placebo. Alirocumab has been evaluated in the Long-Term Safety and Tolerability of Alirocumab in High Cardiovascular Risk Patients with Hypercholesterolemia Not adequately Controlled with Their Lipid Modifying Therapy (ODYSSEY LONG TERM) trial in 2,341 patients at high risk for CHD.[174] Patients were randomly assigned alirocumab 150 mg twice weekly to placebo in addition to maximum tolerated statin therapy with or without additional lipid-lowering therapy. Patients with ASCVD comprised 69% of the trial. At 24 weeks, the percent change in LDL-C reductions with alirocumab compared to placebo was 58% ($p < 0.0001$). This reduction in LDL-C was sustained over a 78-week treatment period.

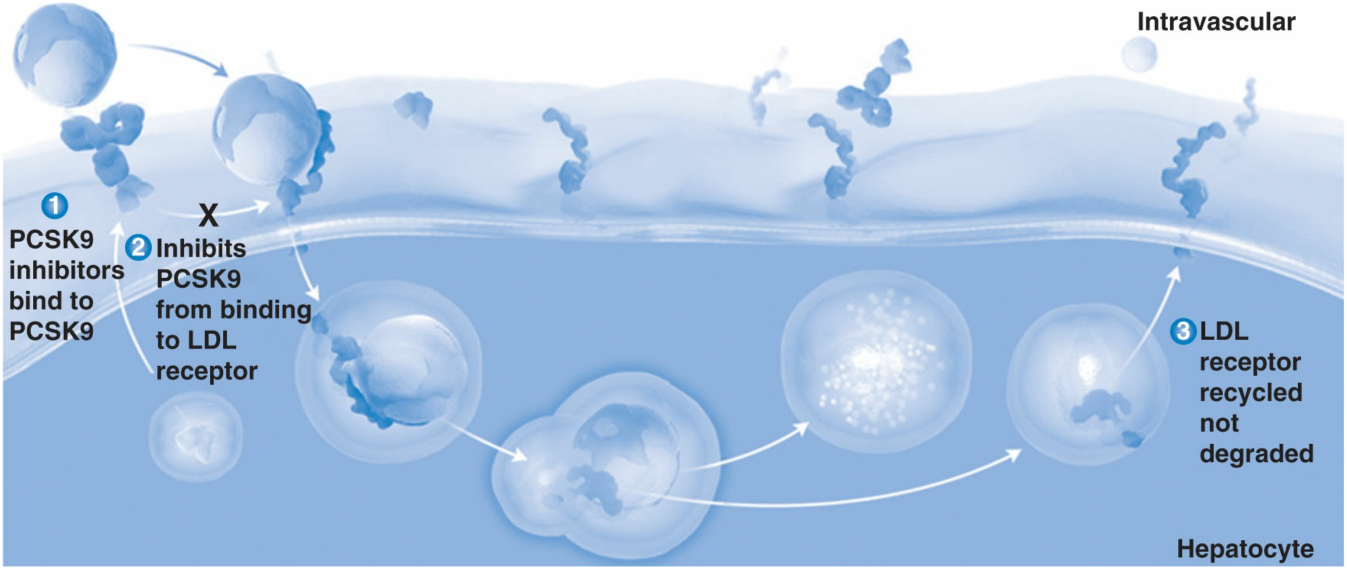

Figure 8-15 Mechanism of action of PCSK9 inhibitors. 1. PCSK9 inhibitors bind to PCSK9 made in the hepatocyte. 2. By binding to the PCSK9 receptor, PCKS9 inhibitors prevent PCSK9-mediated LDL receptor degradation. 3. Secondary to reduce degradation, more LDL receptors are recycled back to the cell surface that subsequently leads to lower LDL-C levels. Used with permission of Amgen.

The FOURIER (Further Cardiovascular Outcomes Research with PCSK9 Inhibition in Subjects with Elevated Risk) was the first trial published to demonstrate reduction in cardiovascular outcomes with the addition of a PCSK9 inhibitor.175 This was a randomized, double-blind, placebo-controlled trial that included 27,564 patients aged 40 to 85 years with clinical ASCVD. Patients were included if they had ASCVD defined as either MI, nonhemorrhagic stroke, or symptomatic peripheral arterial disease [PAD]). Study subjects were also required to have at least one major ASCVD risk factor or two minor risk factors. The minor risk factors were defined as a history of non-MI-related coronary revascularization, residual CAD with $\geq 40\%$ stenosis in ≥ 2 large vessels, HDL-C <40 mg/dL for men and <50 mg/dL for women, high-sensitivity C-reactive protein [hs-CRP] >2 mg/L, LDL-C ≥ 130 mg/dL or non–high-density-lipoprotein cholesterol [non-HDL-C] ≥ 160 mg/dL, or metabolic syndrome). Patients also had to have a fasting LDL-C level >70 mg/dL or a non-HDL-C levels ≥ 100 mg/dL after ≥ 4 weeks of stable dose of atorvastatin 20, 40, or 80 mg daily, with or without ezetimibe, and fasting TG ≤ 400 mg/dL. The median LDL-C at baseline was 92 mg/dL. Patients were randomized to receive evolocumab administered subcutaneously at a dose of 140 mg every 2 weeks (or 420 mg monthly) or matching placebo. The median duration of therapy was 2.2 years. The results demonstrated that treatment with evolocumab significantly reduced the risk of the primary endpoint (composite of cardiovascular death, MI, stroke, hospitalization for unstable angina, or coronary revascularization) (hazard ratio, 0.85; 95% confidence interval [CI], 0.79 to 0.92, $P < 0.001$) and the key secondary endpoint (cardiovascular death, MI, or stroke) (hazard ratio, 0.80; 95% CI, 0.73 to 0.88; $P < 0.001$). The degree of risk reduction in cardiovascular death, MI, or stroke increased over time, from 16% in the first year of follow-up to 25% after 1 year. In terms of LDL-C reduction, at 48 weeks, the mean LDL-C was reduced by 59% (mean 56 mg/dL). Approximately 87% of patients achieved an LDL-C of <70 mg/dL. Additionally, 67% of patients had LDL-C levels <40 mg/dL, and 42% reached levels of <25 mg/dL. There was a slightly higher rate of injection-site reactions in the patients receiving evolocumab compared with placebo (2.1% vs. 1.6%).

Both alirocumab and evolocumab have been evaluated in patients with HeFH.[176–178] All patients in these studies were on maximally tolerated doses of statins. In the combined studies evaluating alirocumab, patients had an average baseline LDL-C of 141 mg/dL. Patients were treated for 12 weeks with alirocumab 75 mg every 2 weeks or placebo. At the end of the treatment period, the mean LDL-C reduction observed with alirocumab was 48%. As with other studies with alirocumab, if additional LDL-C lowering was needed patients were given an additional 12 weeks of therapy with an increased dose of 150 mg every 2 weeks. Following an additional 12 weeks of treatment, the mean LDL-C reduction from baseline was 54% ($p < 0.0001$). Almost half (42%) of the study population received the higher dose. Evolocumab was evaluated in the patient population in the RUTHERFORD-2 trial.[178] Patients were randomized to receive 140 mg every 2 weeks of evolocumab, or 420 mg once monthly or placebo. The mean baseline LDL-C was 156 mg/dL with 76% on high-intensity statin therapy. Following 12 weeks of therapy, evolocumab reduced baseline LDL-C by 61% with twice-weekly dosing and 62% with monthly dosing ($p < 0.0001$).

Evolocumab has been studied in patients with HoFH in the Trial Evaluating PCSK9 Antibody in Subjects with LDL Receptor Abnormalities (TESLA- Part B).[179] This was a multicenter, double-blind, randomized, placebo-controlled, 12-week trial in 49 patients. Patients received 420 mg monthly of evolocumab or placebo. The mean LDL-C at baseline was 349 mg/dL. All patients were on either atorvastatin or rosuvastatin with 92% also being on ezetimibe. Following 12 weeks of treatment with evolocumab, the mean decrease in LDL-C from baseline was 31% ($p < 0.0001$).

PHARMACOKINETICS/PHARMACODYNAMICS

Alirocumab and evolocumab are both human monoclonal IGg2 antibodies and therefore must be administered via subcutaneous injection to exert an effect. Maximum suppression of PCSK9 occurs in approximately 4 hours with evolocumab and 4 to 8 hours with alirocumab. Maximum serum concentrations reached in 3 to 4 days with evolocumab and 3 to 7 days with alirocumab. The volume of distribution for both agents is small; therefore, these agents are expected to stay in the extracellular space. Alirocumab is eliminated through degradation to small peptides and amino acids while evolocumab is cleared based on its concentration. At low concentrations it is cleared primarily thru saturable binding to PCSK9 and at higher concentrations it is eliminated via a

---

non-saturable proteolytic pathway. The half-life of alirocumab is 17 to 20 days and 11 to 17 days for evolocumab.

ADVERSE EFFECTS

The most common adverse effects reported in the 52 weeks study with evolocumab were nasopharyngitis, upper respiratory tract infection, influenza, back pain, and injection site reactions. However, the difference in the incidence compared to placebo is relatively small. The most common injection site reactions were erythema, pain, and bruising. The most common adverse effect leading to discontinuation was myalgia that occurred in 0.3% of evolocumab patients and 0% in those receiving placebo. In pooled studies the types of adverse effects reported were relatively similar. Allergic reactions occurred in 5.1% of evolocumab-treated patients and 4.6% in those treated with placebo. Neurocognitive events were reported in less than 0.2% of patients. Hypersensitivity reactions such as rash and urticaria were also reported in 1% and 0.4%, respectively, with cases resulting in discontinuation of therapy. The adverse reactions reported with alirocumab were nasopharyngitis, injection site reactions, influenza, and urinary tract infection. The main adverse effects associated with discontinuation were allergic reactions (0.6% vs. 0.2% for placebo) and elevated liver enzymes (0.3% vs. <0.1% for placebo). Injection site reactions were similar to those reported with evolocumab. Neurocognitive events were reported in 0.8% of patients treated with alirocumab compared to 0.7% for placebo. Hypersensitivity reactions also occurred with alirocumab. However, hypersensitivity vasculitis as well as hypersensitivity reactions requiring hospitalizations were reported with alirocumab but not with evolocumab. Neutralizing antibodies were detected in 1.2% of patients treated with alirocumab, and no cases were reported in patients taking evolocumab. However, the long-term consequences from developing neutralizing antibodies are currently unknown.

PLACE IN THERAPY

Both alirocumab and evolocumab are indicated as an adjunct to diet and maximally tolerated statin therapy in patients with HeFH or clinical ASCVD, who require additional reductions in LDL-C. These agents should be considered as either add-on therapy to patients already on statin therapy who need additional LDL-C lowering, or in patients who are deemed statin intolerant.[100] Evolocumab is also indicated for use in combination with other lipid-lowering therapies including LDL apheresis in patients with HoFH who require additional lowering in LDL-C. Alirocumab is administered as a dose of 75 mg every 2 weeks and may be increased in 4 to 8 weeks to 150 mg every 2 weeks if additional LDL-C lowering is required. Evolocumab is dosed at 140 mg every 2 weeks or 420 mg once monthly for HeFH and those with primary hypercholesterolemia with clinical ASCVD. In patients with HoFH, the dose is 420 mg once monthly. Alirocumab has only been studied in patients over the age of 18, while evolocumab may be used in the adolescent population with HoFH aged 13 to 17. Neither agent requires a dose adjustment in patients with mild to moderate renal insufficiency. No data are available for patients with CrCl < 30 mL/minute. Since these proteins do not rely upon the kidneys as a method of excretion, they can likely be used in patients with low CrCl, including those undergoing hemodialysis. However, the PCSK9 inhibitors have not been studied in this patient population. Additionally, since they are large molecules, it is unlikely they would be removed by hemodialysis. No dose adjustment is necessary in patients with hepatic impairment.

CLINICAL PEARLS

Allow evolocumab injections to warm at room temperature for at least 30 minutes prior to use and alirocumab 30 to 40 minutes prior to use.

Do not warm evolocumab by any other means than setting at room temperature (e.g., rolling between hands).

If you miss a dose of evolocumab and the time to next dose is greater than 7 days, administer the dose. If less than 7 days, hold the dose and get back on usual schedule.

Evolocumab and alirocumab may be injected into the thigh, abdomen, or upper arm.

Evolocumab can remain at room temperature but expires in 30 days.

Alirocumab should not be left unrefrigerated for greater than 24 hours.

Essential Hypertension

Judy W. Cheng

CORE PRINCIPLES

		CHAPTER CASES
1	A diagnosis of hypertension is based on the mean of two or more properly measured seated blood pressure (BP) measurements taken on two or more occasions.	**Case 9-1 (Questions 1, 2), Table 9-1, Table 9-4, Figure 9-1**
2	Most patients with hypertension have a recommended BP goal of less than 140/90 mm Hg (including those with diabetes or chronic kidney disease [CKD] under age 70 years). Elderly patients (age > 60 years) have a higher BP goal of less than 150/90 mm Hg (see core principle #7).	**Case 9-1 (Questions 6, 7, 8), Figure 9-2**
3	Lifestyle modifications are the foundation for preventing hypertension, and they are an important component of first-line therapy in all patients treated with antihypertensive drug therapy.	**Case 9-1 (Questions 11, 12, 13), Table 9-5**
4	Evidence supports the use of an angiotensin-converting enzyme inhibitor (ACEI), angiotensin receptor blocker (ARB), calcium-channel blocker (CCB), or thiazide diuretic as first-line therapy to prevent cardiovascular (CV) events for most patients.	**Case 9-1 (Questions 9, 14, 15), Case 9-3 (Question 2), Case 9-4 (Questions 1-9), Case 9-6 (Questions 1-3 and 6-10), Figure 9-2, Table 9-8, Table 9-9, Table 9-11, Table 9-12, Table 9-13**
5	In black population, including those with diabetes, evidence supports the use of thiazide diuretics and CCB.	**Case 9-1 (Questions 16, 17), Case 9-5 (Question 1) Case 9-6 (Question 4)**
6	Pharmacotherapy recommendations for patients with hypertension and other comorbidities are specifically based on evidence demonstrating reduced risk of CV events.	**Case 9-1 (Question 10), Case 9-3 (Questions 2, 4) Case 9-7 (Question 2), Table 9-7**
7	Elderly patients with hypertension should be managed using the same general treatment principles that apply to all patients with hypertension. However, their BP goal is higher (less than 150/90 mm Hg) unless they also have CKD and age younger than 70 years. In such case, their BP goal is less than 140/90 mm Hg.	**Case 9-2 (Questions 1, 2)**

8 In the population aged ≥18 years with CKD and age under 70 years, evidence supports initial (or add-on) antihypertensive treatment to include an ACEI or ARB to improve renal outcomes. This applies to all CKD patients with hypertension regardless of race or diabetes status.	**Case 9-3 (Questions 1, 3), Case 9-6 (Question 5)**
9 If goal BP is not attained within a month of treatment, increase the dose of the initial drug or add a second drug (ACEI, ARB, CCB, or thiazide diuretic). If goal BP cannot be reached with two drugs, add and titrate a third drug. If goal BP cannot be reached using only the drugs recommended as first line, because of a contraindication or the need to use more than three drugs to reach goal BP, antihypertensive drugs from other classes can be used. Referral to a hypertension specialist may be indicated.	**Case 9-4 (Question 10), Case 9-5 (Question 1) Case 9-8 (Questions 1–3) Case 9-9 (Questions 1–4) Case 9-10 (Questions 1–3) Case 9-11 (Questions 1–4) Case 9-12 (Questions 1–4) Table 9-2, Table 9-3, Table 9-10, Table 9-14, Table 9-15**

INTRODUCTION

Approximately 80 million Americans have hypertension, also called high blood pressure (BP).[1] It is estimated that approximately 33% of adult Americans have hypertension, making it the most frequently encountered chronic medical condition. About 77% of those are using antihypertensive medication, but only 54% of those are controlled (defined as both systolic BP [SBP] <140 mm Hg and diastolic BP [DBP] <90 mm Hg). It is also one of the most significant risk factors for cardiovascular (CV) morbidity and mortality resulting from target-organ damage to blood vessels in the heart, brain, kidney, and eyes. These complications can manifest as either atherosclerotic vascular disease or other forms of CV disease. The exact etiology of essential hypertension is unknown; however, lifelong management with lifestyle modifications and pharmacotherapy are usually needed.

Blood Pressure

During systole, the left ventricle contracts, ejecting blood systemically into the arteries causing a sharp rise in arterial BP. This is the systolic BP. The left ventricle then relaxes during diastole, and arterial BP decreases to a trough value as blood returns to the heart from the venous system. This is the diastolic BP. When recording BP (e.g., 120/76 mm Hg), the numerator is the SBP and the denominator is the DBP. BP has a predictable diurnal rhythm, with fluctuations throughout the day. Values are lowest during the nighttime, sharply rise starting in the early morning, and peak in the late morning to early afternoon.

Mean arterial pressure (MAP) is sometimes used to represent BP, especially in patients with hypertensive emergency. MAP collectively reflects both SBP and DBP, with one-third of the pressure from SBP and two-thirds from DBP. It is calculated using the following equation (Eq. 9-1):

$$\text{MAP} = (\text{SBP} \times 1/3) + (\text{DBP} \times 2/3) \qquad \text{(Eq. 9-1)}$$

Hypertension is defined as an elevated SBP, DBP, or both. A clinical diagnosis of hypertension is based on the mean of two or more properly measured seated BP measurements taken on two or more occasions. Since 1976, the National Heart Lung and Blood Institute has collaborated with researchers and practitioners to develop clinical practice guidelines focused on the management of hypertension (The Joint National Commission [JNC]). In late 2013, the eighth edition of the JNC guidelines were released.[2] Unlike previous editions of the JNC guidelines, definitions and staging of BP were not addressed, but thresholds for pharmacologic treatment were defined, which will be discussed here.

PATHOPHYSIOLOGY OF BLOOD PRESSURE REGULATION

Various neural and humoral factors are known to influence and regulate BP. [3] These include the adrenergic nervous system (controls α- and β-adrenergic receptors), the renin–angiotensin–aldosterone system (RAAS) (regulates systemic and renal blood flow), renal function and renal blood flow (influences fluid and electrolyte balance), several hormonal factors (adrenal cortical hormones, vasopressin, thyroid hormone, and insulin), and the vascular endothelium (regulates release of nitric oxide [NO], bradykinin, prostacyclin, and endothelin). Knowledge of these mechanisms is important in understanding antihypertensive drug therapy. BP is normally regulated by compensatory mechanisms that respond to changes in cardiac demand. An increase in cardiac output (CO) normally results in a compensatory decrease in total peripheral resistance (TPR); likewise, an increase in TPR results in a decrease in CO. These events regulate MAP, as is represented in the following equation (Eq. 9-2):

$$\text{MAP} = \text{CO} \times \text{TPR} \qquad \text{(Eq. 9-2)}$$

Adverse changes in BP can occur when these compensatory mechanisms are not functioning properly. It has been suggested that in hypertension an initial increase in fluid volume increases CO and arterial pressure. Eventually, with long-standing hypertension, it is believed that TPR increases so that CO returns to normal.

The kidney plays an important role in the regulation of arterial pressure, especially through the RAAS. Decreases in BP and renal blood flow, volume depletion or decreased sodium concentration, and an activation of the sympathetic nervous system can all trigger an increased secretion of the enzyme renin from the cells of the juxtaglomerular apparatus in the kidney. Renin acts on angiotensinogen to catalyze the formation of angiotensin I. Angiotensin-converting enzyme (ACE) converts angiotensin I to angiotensin II (see Figs. 14-2 and 14-6 in Chapter 14, Heart Failure). Angiotensin II is a potent vasoconstrictor that acts directly on arteriolar smooth muscle and also stimulates the production of aldosterone by the adrenal glands. Aldosterone causes sodium and water retention and the excretion of potassium. Several factors influence renin release, especially those that alter renal perfusion. The resultant increase in BP results in suppression of renin release through negative feedback.

Approximately 20% of patients with essential hypertension have lower-than-normal plasma renin activity (PRA), whereas approximately 15% have PRA concentrations that are higher than normal. Those with normal to high PRA (e.g., young and whites) should theoretically be more responsive to drug therapies that target the RAAS (e.g., ACE inhibitors and angiotensin receptor blockers [ARBs]). Patients with low PRA may be more responsive to diuretic therapy. However, routinely measuring PRA as a strategy to guide empiric drug selection has limited clinical utility and does not generally result in an outcome superior to careful selection of antihypertensive drug therapy.

Arterial BP is also regulated by the adrenergic nervous system, which causes contraction and relaxation of vascular smooth muscle. Stimulation of α-adrenergic receptors in the central nervous system (CNS) results in a reflex decrease in sympathetic outflow, causing a decrease in BP. Stimulation of postsynaptic α_1-receptors in the periphery causes vasoconstriction. The α-receptors are regulated by a negative feedback system; as norepinephrine is released into the synaptic cleft and stimulates presynaptic α_2-receptors, further norepinephrine release is inhibited. This negative feedback results in a balance between vasoconstriction and vasodilatation. Stimulation of postsynaptic β_1-receptors located in the myocardium causes an increase in heart rate and contractility, whereas stimulation of postsynaptic β_2-receptors in blood vessels results in vasodilation.

A direct association exists between sodium and BP. Although there is a considerably high degree of patient variability in BP sensitivity to sodium (likely affected by heredity and interactions with other environmental exposures), patients with a high dietary sodium intake generally have a greater prevalence of hypertension than those with a low sodium intake. The mechanism by which excess sodium intake contributes to hypertension is uncertain, but it is believed to involve an undetermined natriuretic hormone (not the A- and B-type natriuretic peptides associated with heart failure) that may be induced as a consequence of impaired renal sodium excretion. This natriuretic hormone might also cause an increase in intracellular sodium and calcium, resulting in increased vascular tone and hypertension. The consequences of impaired sodium excretion may have an underlying evolutionary basis. Human physiology evolved in a “hunter-gatherer” society with diets characterized by low sodium and high potassium. The relatively recent shifts in diet patterns brought about by the advent of modern food processing, coupled with increased survival beyond reproductive years, may not have made it possible for modern humans to adapt successfully to high sodium exposure.

Epidemiologic evidence and clinical trials have demonstrated an inverse relationship between calcium and BP. One proposed mechanism for this relationship involves an alteration in the balance between intracellular and extracellular calcium. Increased intracellular calcium concentrations can increase peripheral vascular resistance (PVR), resulting in increased BP.

A decrease in dietary potassium has been associated with an increase in PVR. In theory, diuretic-induced hypokalemia could counteract some of the antihypertensive effects of diuretic therapy, but this has not been seen in clinical trials. It is important, however, that potassium concentrations be maintained within the normal range because hypokalemia increases the risk of CV events, such as sudden death.

Insulin resistance and hyperinsulinemia also have been associated with hypertension. Kaplan[3] suggests that insulin resistance is responsible for the frequent coexistence of hyperglycemia, dyslipidemia, hypertension, and abdominal obesity (also called the metabolic syndrome).[4] The exact role of insulin resistance in the development of hypertension is still evolving.

The vascular epithelium is a dynamic system in which vascular tone is regulated by numerous substances. As noted previously, angiotensin II promotes vasoconstriction of the vascular epithelium. However, several other substances regulate vascular tone. NO is produced in the endothelium and is a potent vasodilatory chemical that relaxes the vascular smooth muscle. Hypothetically, some patients with hypertension have an intrinsic deficiency in NO release and inadequate vasodilation, which could contribute to hypertension and its vascular complications.

Factors that regulate BP are well understood and continue to evolve, but the cause of essential hypertension is still unknown. It is impossible to target therapy to specific abnormalities. Therefore, antihypertensive therapy should be selected based on evidence from clinical trials that have demonstrated reductions in hypertension-associated complications, as is discussed later in this chapter.

CARDIOVASCULAR RISK AND BLOOD PRESSURE

Direct correlations between BP values and risk of CV disease have been established based primarily on epidemiologic data. Beginning at a benchmark BP of 115/75 mm Hg, the risk of CV disease doubles with every increment of 20/10 mm Hg.[4] Clinically, it is important to note that incremental elevations in SBP are more predictive of CV disease than elevations in DBP, especially for patients older than 50 years of age. Therefore, SBP is the target of evaluation and intervention for most patients with hypertension. In younger patients with hypertension, elevated DBP may be the only BP abnormality present.

MEASURING BLOOD PRESSURE

Auscultatory Method

The measurement of BP should be standardized to minimize variability in readings. The American Heart Association (AHA) technique for auscultatory BP measurement (Table 9-1)[5] should be used in most patients.[6]

For a video demonstrating methods for measuring BP in adults (courtesy of the University of Colorado School of Pharmacy), go to http://www.youtube.com/watch?v=Blqei6_s6J0&list=UUPLXxewjAvEBrO9DuLERbbQ.

Correct BP measurements require that the clinician listen through a stethoscope that is placed over the brachial artery for the appearance of the five phases of the Korotkoff sounds. Each sound has distinct features, which are depicted in Figure 9-1.[6] Examples of Korotkoff sounds can be found in the Thinklabs Medical Sound Library (http://www.thinklabsmedical.com/stethoscope_community/Sound_Library) under Blood Pressure—Korotkoff Sounds 1 and Blood Pressure—Korotkoff Sounds 2.

Table 9-1

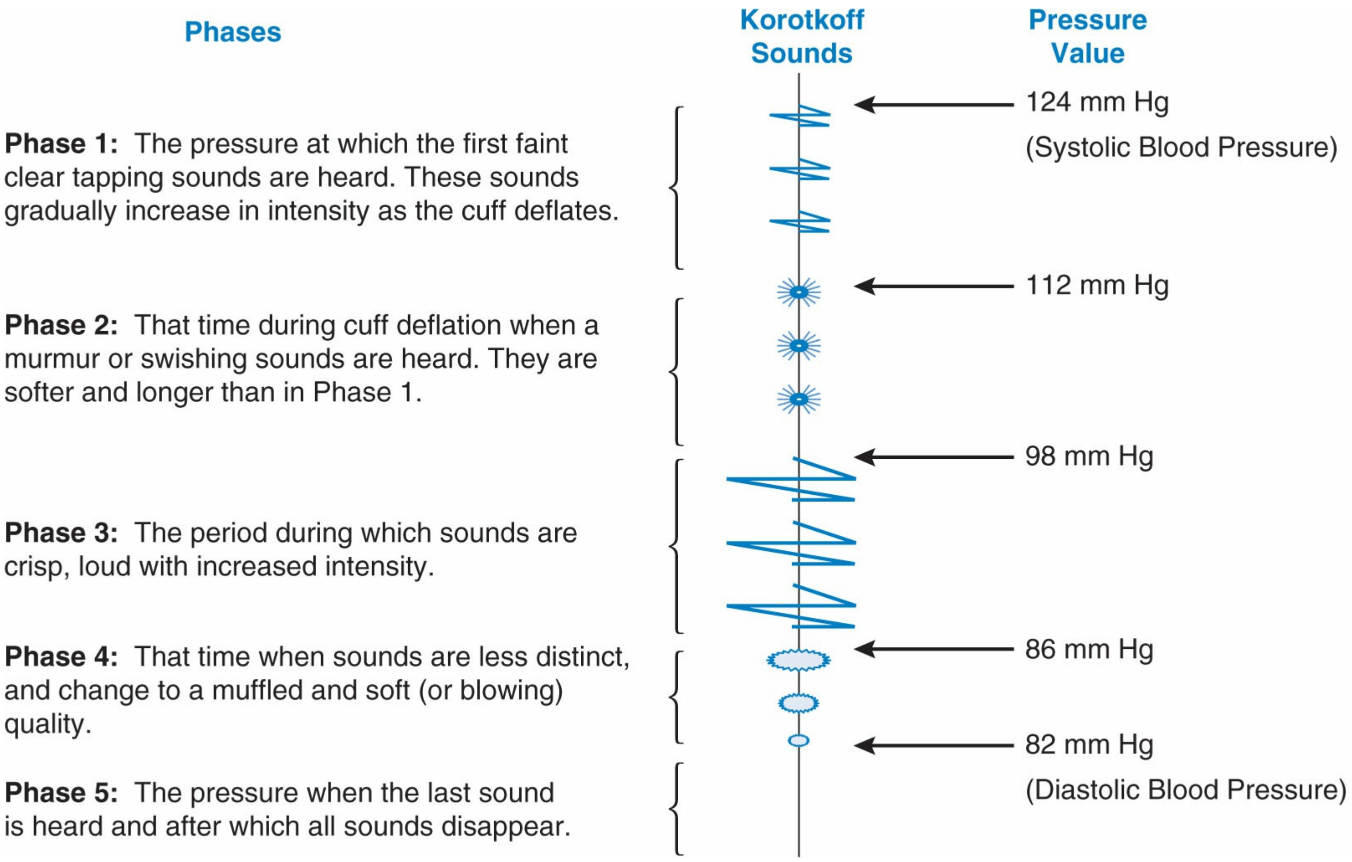
Auscultatory Method for Blood Pressure Measurement in Adults as Recommended by the American Heart Association[5]

1. **PATIENT:** Patient should be seated for 5 minutes with arm bared, unrestricted by clothing, and supported at heart level. Smoking or food ingestion should not have occurred within 30 minutes before the measurement
2. **CUFF:** An appropriately sized cuff should be used. The internal inflatable bladder width should be at least 40% of the bladder length and cover at least 80% of the upper arm circumference. The cuff should be wrapped snugly around the arm with the center of the bladder over the brachial artery
3. **MONITOR:** Measurements should be taken with a correctly calibrated mercury sphygmomanometer, an aneroid manometer, or a validated electronic device
4. **PALPATORY METHOD:** SBP should be estimated using the palpatory method. The cuff is rapidly inflated in 10-mm Hg increments, while simultaneously palpating the radial pulse on the patient’s wrist on the cuffed arm and observing the manometer. The pressure when the radial pulse is no longer palpable is the estimated SBP. The cuff is then deflated rapidly
5. **KOROTKOFF SOUNDS:** The head of the stethoscope, ideally using the bell, should be placed over the brachial artery, with each earpiece in the clinician’s ear. The cuff should then be rapidly inflated to 20–30 mm Hg above the estimated SBP from the palpatory method. The cuff is slowly deflated at a rate of 2 mm Hg/second while the clinician simultaneously listens for phase 1 (the first appearance of sounds) and phase 5 (the disappearance of sounds) Korotkoff sounds while also observing the manometer. When the pressure is 10 to 20 mm Hg below phase 5, the cuff can be rapidly deflated
6. **DOCUMENTATION:** BP values should always be recorded. The BP values (SBP/DBP) should be recorded using even numbers (rounded up from an odd number)[a] along with the patient’s position (seated, standing, or supine), arm used, cuff size, time, and date
7. **REPEAT:** A second measurement should be taken after at least 1 minute in the same arm. If the readings differ by more than 5 mm Hg, additional measurements should be obtained. The mean of these values should be used to make clinical decisions. BP should be taken in both arms at the initial visit with the BP measured in the arm with the higher reading at subsequent visits

[a]Terminal digit preference (i.e., tendency to report readings that end in 0 or 5) should be avoided.
BP, blood pressure; DBP, diastolic blood pressure; SBP, systolic blood pressure.

Out-of-Office Blood Pressure Monitoring

Home BP measurements can provide information on response to therapy and may help improve adherence to therapy and goal BP achievement in some patients.[7,8] Devices for home measurement should be validated for accuracy according to established protocols from either the British Hypertension Society or the Association for Advancement of Medical Instrumentation. When placed in service, they should be routinely checked against office-based readings for accuracy, especially when readings between office and home are widely discrepant. Patients with average home BP values greater than 135/85 mm Hg are considered hypertensive.[7] Wrist or finger devices that measure BP are generally not accurate and should not be routinely used.



Phase 1: The pressure at which the first faint clear tapping sounds are heard. These sounds gradually increase in intensity as the cuff deflates.

Phase 2: That time during cuff deflation when a murmur or swishing sounds are heard. They are softer and longer than in Phase 1.

Phase 3: The period during which sounds are crisp, loud with increased intensity.

Phase 4: That time when sounds are less distinct, and change to a muffled and soft (or blowing) quality.

Phase 5: The pressure when the last sound is heard and after which all sounds disappear.

Figure 9-1 Phases of the Korotkoff sounds heard when indirectly measuring blood pressure.

Ambulatory blood pressure monitoring (ABPM) typically measures BP every 15 to 30 minutes throughout the day and nighttime using a portable, noninvasive oscillometric device typically worn for 24 hours.[5] This form of specialized monitoring is indicated for patients with suspected white-coat hypertension and may also be helpful in patients with apparent drug resistance, hypotensive symptoms while receiving antihypertensive therapy, episodic hypertension, and autonomic dysfunction.[5] Similar to self-BP measurements, ABPM values are typically lower than office-based measurements. As a comparison, the normal upper limit for BP in most patients is 140/90 mm Hg for office-based measurement, 130/80 mm Hg for ABPM (135/85 mm Hg while awake and 120/75 mm Hg while asleep), and 135/85 mm Hg for self-BP measurements.[5] Therefore, the threshold for normal versus abnormal is lower than that obtained during office-based measurements.

Evidence indicates that ABPM recordings can predict clinical outcomes more strongly than office-based BP measurements, most likely because the device factors in BP throughout nighttime hours, which provides a more accurate reflection of the overall average pressure load.[9] However, in clinical practice ABPM is not recommended for routine evaluation of responses to treatment for a number of reasons, including lack of widespread availability, cost, and intrusiveness of performing multiple ABPM sessions in the same patient.[5]

BP values measured outside the office should be considered in the overall treatment of patients with hypertension. However, it is important to acknowledge that office-based BP measurements have been the source used in the major clinical trials establishing that treatment of hypertension reduces morbidity and mortality rates. Therefore, they are still considered the standard values that should guide evaluation of response to antihypertensive drug therapy in most patients.

The reliability and accuracy of automated BP monitors, whether they are used in the office or out of the office, can vary significantly. For a summary of commercially available automatic monitors and whether they have passed validation protocols, please refer to the dabl Educational Trust website (http://www.dableducational.org). The use of BP measurements from automated machines commonly found in grocery stores and pharmacies may have questionable reliability. Measurements using these publically available machines should not be relied on to make clinical decisions, but should be used to direct patients for follow-up with their medical provider as a screening tool.

Types of Hypertension

ESSENTIAL HYPERTENSION

Most patients with hypertension have essential hypertension (also known as primary hypertension), in which there is no identifiable cause for their chronically elevated BP.

SECONDARY HYPERTENSION

Patients with secondary hypertension have a specific identified cause for elevated BP (Table 9-2). Although only 5% to 10% of those among the hypertensive population have causes that are purely secondary, further diagnostic evaluation should occur if physical or laboratory findings suggest the possibility of a secondary cause (Table 9-3).[3,10,11] Some secondary causes are potentially reversible and may normalize BP (e.g., coarctation of the aorta), whereas others are more often superimposed on and worsen an already elevated BP (e.g., obstructive sleep apnea). The distinction is important because treatment of an underlying cause may not always be expected to completely normalize BP and allow discontinuation of antihypertensive therapies. In patients who have resistant hypertension (requiring three or more drugs for BP control) or who have a sudden and significant increase in BP, further diagnostic workup for secondary causes should be considered.

WHITE-COAT HYPERTENSION

White-coat hypertension describes patients who have consistently elevated BP values measured in a clinical environment in the presence of a health care professional (e.g., physician's office), yet when measured elsewhere or with 24-hour ambulatory monitoring, BP is not elevated.[5,6] Home BP monitoring or 24-hour ABPM is warranted in patients suspected of having white-coat hypertension to differentiate this from true hypertension.[5] The commonly used definition is a persistently elevated average office BP of greater than 140/90 mm Hg and an average awake ambulatory reading of less than 135/85 mm Hg.[8] The label white-coat hypertension applies only to patients without target-organ disease who are not on antihypertensive therapy.

Table 9-2

Secondary Causes of Hypertension[10]

Alcoholism
Chronic kidney disease
Chronic steroid therapy and Cushing syndrome
Coarctation of the aorta
Drug induced or drug related: ■ Amphetamines (amphetamine, dexmethylphenidate, dextroamphetamine, lisdexamfetamine, methylphenidate, phendimetrazine, and phentermine) ■ Antidepressants (bupropion, desvenlafaxine, and venlafaxine) ■ Antihypertensive agents that are abruptly stopped (only β-blockers and central a_2-agonists) ■ Anabolic steroids (e.g., testosterone) ■ Calcineurin inhibitors (cyclosporine and tacrolimus) ■ Cocaine and other illicit drugs ■ Corticosteroids (cortisone, dexamethasone, fludrocortisone, hydrocortisone, methylprednisolone, prednisolone, prednisone, and triamcinolone) ■ Ephedra alkaloids ■ Erythropoiesis-stimulating agents (darbepoetin-alfa and erythropoietin) ■ Ergot alkaloids (ergonovine and methysergide)

▪ Estrogen-containing oral contraceptives (ethinyl estradiol) ▪ Licorice (including some chewing tobacco) ▪ Monoamine oxidase inhibitors (isocarboxazid, phenelzine, tranylcypromine sulfate) when given with tyramine-containing foods or with an interacting drug ▪ Nonsteroidal antiinflammatory drugs (all types) ▪ Oral decongestants (e.g., pseudoephedrine) ▪ Phenylephrine (ocular administration) ▪ Vascular endothelial growth factor inhibitor (bevacizumab) ▪ Vascular endothelial growth factor receptor tyrosine kinase inhibitor (sorafenib and sunitinib)
Pheochromocytoma
Primary aldosteronism
Renovascular disease
Sleep apnea
Thyroid or parathyroid disease

Significant controversies surround white-coat hypertension. Although this does not represent a clinical diagnosis, patients with white-coat hypertension are at risk for eventually developing essential hypertension. Moreover, patients with white-coat hypertension are at a higher risk for CV disease than normotensive patients.[12] The decision to treat or not treat white-coat hypertension is controversial. Many patients enrolled in the landmark clinical trials that demonstrated reductions in CV morbidity and mortality with antihypertensive therapy likely had white-coat hypertension because only office BP measurements were used for inclusion. At minimum, patients with white-coat hypertension should be treated with lifestyle modifications and need to be closely monitored with a device that can measure BP outside the clinic environment if they are not treated with antihypertensive drug therapy.

HYPERTENSIVE CRISES

Hypertensive crises are situations in which measured BP values are markedly elevated (>180/110 mm Hg). They are classified as either a hypertensive emergency (with acute or progressive target-organ damage) or urgency (without acute or progressive target-organ damage). Hypertensive emergencies require hospitalization for immediate BP lowering. Hypertensive urgencies do not require immediate BP lowering; instead, BP should be slowly reduced within 24 hours (but not generally to goal BP so quickly) (see Chapter 16, Hypertensive Crises).

Hypertension Management

Hypertension is treated with both lifestyle modifications and pharmacotherapy. The JNC-8 is considered the “gold standard” consensus guidelines for the management of hypertension in the United States.[2] The overall principle of the guideline is to implement lifestyle modifications in addition to pharmacotherapy to control BP in patients with hypertension. The presence of specific comorbidities in any given patient should be considered when selecting specific pharmacotherapy to treat hypertension. These issues are discussed later in this chapter.

GOALS

The overarching goal of treating patients with hypertension is to reduce associated morbidity and mortality (also called CV events). These manifest as hypertension-associated complications (Table 9-4), which include atherosclerotic vascular disease and other forms of CV disease.

Goal Blood Pressure Values

Achieving goal BP is an important step in the overall treatment of patients with hypertension. According to the JNC-8 guidelines, patients with hypertension of age greater than 18 and less than 60 should have a BP goal of less than 140/90 mm Hg (Figure 9-2).[2]

In contrary to previous editions of the JNC guidelines, where the BP goal for patients with diabetes or chronic kidney disease (CKD) is lower, JNC-8 recommends the same treatment goal for these patients (<140/90 mm Hg).

The change in recommendations is based on some more recent evidence failing to show that more aggressive BP lowering to goal of less than 140/90 mm Hg further improves clinical outcome. There is moderate-quality evidence from three trials (Systolic Hypertension in the Elderly Program [SHEP], Syst-Eur, and UKPDS) that treatment to an SBP goal of lower than 150 mm Hg improves CV and cerebrovascular health outcomes and lowers mortality in adults with diabetes and hypertension.[13–15] However, there are no randomized controlled trials addressing whether treatment to an SBP goal of lower than 140 mm Hg compared with a higher goal (e.g., <150 mm Hg) improves health outcomes in adults with diabetes and hypertension. In the absence of such evidence, the panel recommends a BP goal consistent with the BP goals in the general population younger than 60 years with hypertension. Use of a consistent BP goal in the general population in adults with diabetes of any age may facilitate guideline implementation. This recommendation for an SBP goal of lower than 140 mm Hg in patients with diabetes is also supported by the ACCORD-BP trial, demonstrating[16] no difference in the primary end point of major CV events when patients with type 2 diabetes were treated to an SBP goal of less than 120 mm Hg compared with an SBP goal of less than 120 mm Hg after a mean of 4.7 years. There were also no differences in any of the secondary outcomes except for a reduction in stroke. However, the incidence of stroke in the group treated to lower than 140 mm Hg was much lower than expected, so the absolute difference in fatal and nonfatal stroke between the two groups was only 0.21% per year.

Table 9-3

Clinical Findings Suggestive of Secondary Hypertension

Causes	Historical Findings	Physical Examination Findings	Laboratory Findings
Sleep apnea	Daytime fatigue and somnolence	Large neck circumference; overweight or obese	Abnormal sleep studies with frequent awakenings and anoxic episodes
Renovascular disease	Moderate or severe high BP before age 30 or after 55; rapidly progressive hypertension	Abdominal bruits; funduscopic hemorrhages	Suppressed or stimulated plasma renin activity; IVP (rapid sequence); digital subtraction angiography
Renoparenchymal disease	Dysuria, polyuria, nocturia; urinary tract infections; kidney stones; family history of polycystic or other types of kidney disease	Edema	Proteinuria; hematuria; bacteriuria
Coarctation of the aorta	Intermittent claudication	Diminished or absent femoral pulses compared with carotids; lower SBP in leg compared with arm	—
Pheochromocytoma	Paroxysmal headaches, palpitations, sweating, dizziness, and pallor	Nervousness, tremor, tachycardia, orthostatic hypotension	Clonidine suppression tests[a]; high urinary metanephrine or vanillylmandelic acid
Primary aldosteronism	Weakness, polyuria, polydipsia, intermittent paralysis	Orthostatic hypotension	Hypokalemia
Cushing syndrome	Menstrual irregularity	Moon face; truncal obesity; buffalo hump; hirsutism; violet striae	↑ serum glucose; ↑ plasma cortisol after suppression with dexamethasone

[a] Failure of plasma catecholamines to ↓ by 50% within 3 hours of administration of 0.3 mg clonidine highly suggests pheochromocytoma.

BP, blood pressure; IVP, intravenous pyelogram; SBP, systolic blood pressure

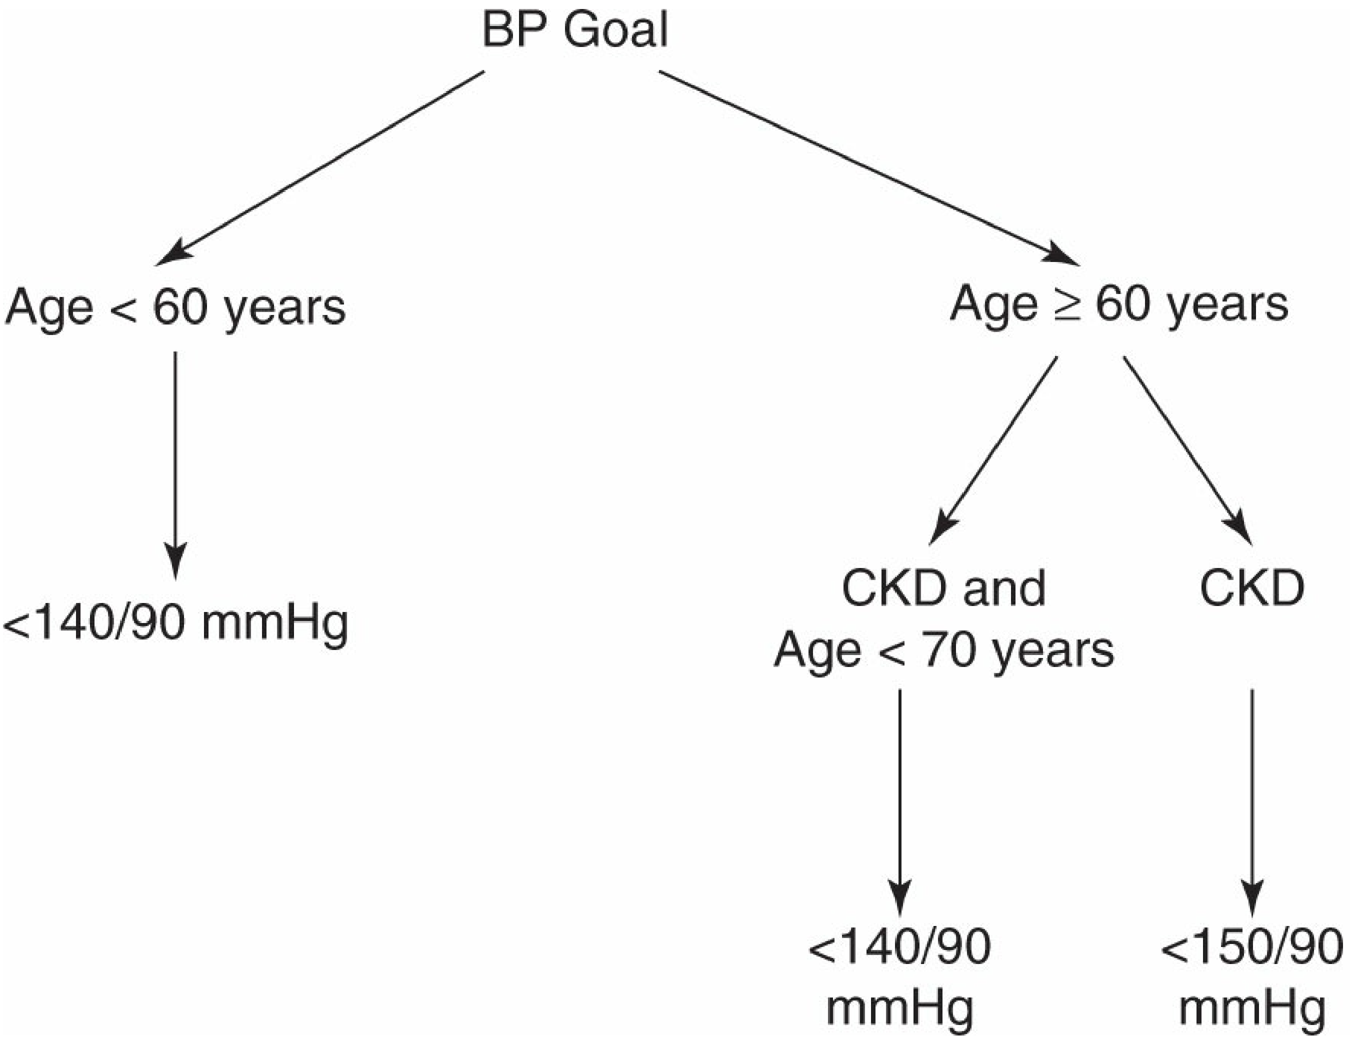


Figure 9-2 Goal blood pressure (BP) determination based on JNC-8, The Eighth Report of the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure.

JNC-8 similarly recommends the same goal DBP in adults with diabetes and hypertension as in the general population (<90 mm Hg). There is no sufficient evidence to support such a lower goal.

Similarly, in patients with CKD, JNC-8 has recommended individuals younger than 70 years with an estimated glomerular filtration rate (GFR) or measured GFR less than 60 mL/minute/1.73 m^2 and people of any age with albuminuria defined as greater than 30 mg of albumin/g of creatinine at any level of GFR to have a BP goal for <140/90 mm Hg. This recommendation is less aggressive than previous JNC guidelines.

The new panel also felt that in adults younger than 70 years with CKD, the evidence is insufficient to determine if there is a benefit in mortality or CV or cerebrovascular health outcomes with antihypertensive drug therapy to a lower BP goal (e.g., <130/80 mm Hg) compared with a goal of lower than 140/90 mm Hg. There is evidence of moderate quality demonstrating no benefit in slowing the progression of kidney disease from treatment with antihypertensive drug therapy to a lower BP goal (e.g., <130/80 mm Hg) compared with a goal of lower than 140/90 mm Hg.[17–19]

It is important to note that the recommendation of BP goal for patients with CKD applies only to those younger than 70 years. Based on current available evidence, JNC-8 cannot make similar recommendation for a BP goal in people aged 70 years or older with GFR less than 60 mL/minute/1.73 m^2. The commonly used estimating equations for GFR were not developed in populations with significant numbers of people older than 70 years and have not been validated in older adults. No outcome trials included large numbers of adults older than 70 years with CKD.

Table 9-4

Hypertension-Associated Complications and Major Cardiovascular Risk Factors

Hypertension-Associated Complications

- Atherosclerotic vascular disease
  - Coronary artery disease (sometimes called coronary heart disease)
    - Myocardial infarction
    - Acute coronary syndromes
    - Chronic stable angina
  - Carotid artery disease
    - Ischemic stroke
    - Transient ischemic attack
  - Peripheral arterial disease
  - Abdominal aortic aneurysm
- Other forms of CV disease
  - Left ventricular dysfunction (systolic heart failure)
  - Chronic kidney disease
  - Retinopathy

Major CV Risk Factors

- Advanced age (>55 years for men, >65 years for women)
- Cigarette smoking
- Diabetes mellitus
- Dyslipidemia
- Family history of premature atherosclerotic vascular disease (men <55 years or women <65 years) in primary relatives
- Hypertension
- Kidney disease (microalbuminuria or estimated GFR <60 mL/minute/1.73 m^2)
- Obesity (BMI $\geq$ 30 kg/m^2)
- Physical inactivity

BMI, body mass index; CV, cardiovascular; GFR, glomerular infiltration rate.

The issue of whether more aggressive BP goals (i.e., <130/80 or <120/80 mm Hg) result in better reductions in risk of CV events than the standard goal of less than 140/90 mm Hg remains an ongoing clinical controversy. Until newer clinical data and newer consensus guidelines are published, it is reasonable for clinicians to follow the BP goals recommended in the JNC-8. The Systolic Blood Pressure Intervention Trial (SPRINT) is a randomized, multicenter clinical trial that is comparing intensive hypertension treatment (SBP goal <120 mm Hg) with standard treatment (SBP goal <140 mm Hg) in approximately 7,500 patients with hypertension and at least one other CV risk factor (patients with a history of diabetes or stroke are excluded). The SPRINT will not be completed until the year 2018 or later, but when completed it will provide further evidence regarding goal BP values.

Another area of controversy is the BP goal value in the very elderly, commonly defined as those 80 years of age or older. JNC-8 recommends that, in the general population aged 60 years or older, hypertension should be treated to a goal of <150/90 mm Hg.[2] However, within this population, the only clear prospective data supporting antihypertensive therapy is from the Hypertension in the Very Elderly Trial (HYVET), which used a BP goal of less than 150/80 mm Hg.[20] It is important to note that BP goals among the elderly are based primarily on expert consensus. BP treatment goal for individual elderly patients to a certain extent should be determined by their frailty and their ability in tolerating side effects of antihypertensive agents (such as orthostatic hypotension).

LIFESTYLE MODIFICATIONS

Lifestyle modifications are the cornerstone of management for preventing and treating hypertension. AHA guidelines for lifestyle modifications recommend both diet and exercise.[21,22] These recommendations are summarized in Table 9-5. Engaging in these modifications is encouraged for all persons to prevent the development of hypertension; however, they are recommended as a component of first-line therapy in all patients with prehypertension and in all patients with a diagnosis of hypertension regardless of whether their BP values are at goal or not.[2] Independent of BP lowering, CV risk may also be reduced.

Table 9-5

Lifestyle Modifications to Prevent and Treat Hypertension[20,21]

Modification	Recommendation
Weight management	Lose weight if overweight or obese, ideally attaining a BMI <25 kg/m^2 Maintain a desirable BMI (18.5–24.9 kg/m^2) if not overweight or obese
Adopt DASH-type dietary patterns	Consume a diet that is rich in fruits and vegetables (8–10 servings/day), rich in low-fat dairy products (2–3 servings/day), but has reduced amounts of saturated fat and cholesterol
Reduced sodium intake	Reduce daily dietary sodium intake as much as possible, ideally to <65 mmol/day (equal to 1.5 g/day sodium or 3.8 g/day sodium chloride)
Increased dietary potassium intake	Increase daily dietary potassium intake to 120 mmol/day (4.7 g/day), which is the amount provided in a DASH-type diet

Moderation of alcohol consumption	For patients who drink alcohol, limit consumption to no more than two drinks per day in men and no more than one drink per day in women and lighter-weight people.[a] Do not recommend alcohol consumption in patients who do not drink alcohol
Regular physical activity	Regular moderate-intensity aerobic physical activity; at least 30 minutes of continuous or intermittent 5 day/week, but preferably daily

[a] One drink is defined as 12 ounces of regular beer, 5 ounces of wine (12% alcohol), and 1.5 ounces of 80-proof distilled spirits.

BMI, body mass index; DASH, Dietary Approaches to Stop Hypertension.

Weight Reduction

Weight loss as small as 5% to 10% of body weight in overweight individuals may significantly lower CV risk. For most patients, an average weight loss of 10 kg can reduce SBP by 5 to 20 mm Hg, a reduction comparable to that achieved from the addition of an antihypertensive drug used as monotherapy.[2]

DASH Eating Plan

The DASH (Dietary Approaches to Stop Hypertension) diet is rich in fruits, vegetables, and low-fat dairy foods, coupled with reduced saturated and total fat.[23] The patient education publication entitled "Your Guide to Lowering Your Blood Pressure with DASH" can be found at http://www.nhlbi.nih.gov/health/public/heart/hbp/dash/index.htm. The DASH diet can substantially reduce BP (8–14 mm Hg in SBP for most patients) and yield similar results to single-drug therapy. The low-fat component of this diet is important because weight loss is more readily achieved by a reduced-calorie diet (fats contribute more calories per gram than

do either carbohydrates or protein) and lowered fat intake also reduces the risk of CV disease by lowering cholesterol.

Dietary Sodium Restriction

The average American intake of sodium is more than 6 g/day. Restricting sodium should be encouraged for patients with prehypertension or hypertension, and the current recommendation to restrict daily sodium intake to no more than 1.5 g is lower than what has traditionally been suggested. Some clinicians may argue that the efficacy of implementing sodium restriction in patients with hypertension may vary. Evidence from clinical trials has shown, however, that sodium restriction provides mean reductions in BP of 5/2.7 mm Hg in patients with hypertension.[23] Restricting sodium to less than 1.5 g daily has been shown to decrease SBP by more than 20 mm Hg in patients with resistant hypertension.[24] Some populations (diabetic patients, blacks, and elderly persons) respond better to sodium restriction than the general population, but all patients with hypertension should be instructed to reduce their sodium intake. They should be counseled not to add salt to foods and to avoid or minimize ingestion of processed or packaged foods, foods with high sodium content, and nonprescription drugs containing sodium.

Increased Potassium Intake

Increasing dietary potassium intake is recommended, although it is not commonly identified by most patients as a dietary modification that will lower BP. Adhering to a DASH eating plan will usually assure an intake of the recommended 4.7 g daily. Dietary supplementation should be the primary strategy to increase potassium. Implementing potassium supplementation outside of dietary sources for the sole purpose of lowering BP should be avoided because of the potential harm from hyperkalemia. Moreover, potassium supplementation in patients with hypertension who are treated with a potassium-sparing diuretic, aldosterone antagonist, ACEI, or an ARB may cause hyperkalemia. This can also occur in patients with hypertension and CKD who are treated with potassium supplementation.

Moderate Alcohol Consumption

Explaining the need to limit alcohol consumption is complicated. Whereas data suggest that small daily doses of alcohol (e.g., one glass of red wine with dinner) are associated with lower CV risk, excessive alcohol intake can elevate BP, decrease the effectiveness of antihypertensive medications, and increase the risk of stroke. Patients who consume three to four drinks per day experience a 3- to 4-mm Hg increase in SBP and a 1- to 2-mm Hg increase in DBP compared with those who do not drink. These increases are even higher in patients who consume more alcohol. Moderate alcohol consumption of two or fewer drinks daily in men and one or fewer drinks daily in women or lighter-weight individuals can decrease SBP approximately 2 to 4 mm Hg. Patients should be instructed that one drink is equal to 1.5 ounces of 80-proof whiskey, 5 ounces of wine, or 12 ounces of beer.

Physical Activity

Regular physical activity can reduce SBP by 4 to 9 mm Hg in most patients.[2] Benefits include reducing the incidence of hypertension, assisting weight loss and weight loss maintenance, and improving overall CV fitness. Most patients with hypertension can safely increase their regular aerobic activity. Those with more severe forms of target-organ damage (e.g., angina and previous MI) may, however, need a medical evaluation before increasing their activity level. Physical activity should ideally occur for at least 30 minutes, at least 5 days of the week, but preferably daily. Walking, running, cycling, swimming, and cross-country skiing are examples of aerobic exercise that are recommended for physical activity.

PHARMACOTHERAPY

Numerous clinical trials have demonstrated that antihypertensive pharmacotherapy reduces the risk of hypertension-associated complications (e.g., CV morbidity and mortality). This evidence is the foundation for JNC-8 consensus guidelines, which provide specific evidence-based pharmacotherapy recommendations based on patient-specific medical history and CV risk.

JNC-8 guidelines recommend that in the general nonblack population, including those with diabetes, initial antihypertensive treatment should include a thiazide-type diuretic, calcium-channel blocker (CCB), ACEI, or ARB. In the general black population, including those with diabetes, initial antihypertensive treatment should include a thiazide-type diuretic or CCB. In the population aged ≥18 years with CKD, initial (or add-on) antihypertensive treatment should include an ACEI or ARB to improve kidney outcomes. This applies to all CKD patients with hypertension regardless of race or diabetes status. Evidence obtained since the 2003 JNC-7 guidelines demonstrates that, for first-line treatment in primary prevention patients, β-blocker therapy is not as effective in reducing CV events compared with ACEI, ARB, CCB, or thiazide diuretic therapy.[25] Therefore, unlike previous versions of the JNC guidelines, β-blocker is no longer recommended as one of the first-line treatment option. Moreover, newer evidence also suggests that the reductions in CV events with ACEI, ARB, CCB, or thiazide diuretic are comparable, so that one agent is not automatically preferred over another.[26] Unlike previous versions of JNC guidelines, JNC-8 guidelines also did not discuss selection of antihypertensive agents in patients with specific other comorbidities (aside from diabetes and CKD). Clinicians are to consult treatment guidelines of the specific comorbidities (e.g., heart failure and coronary artery disease) to help make treatment decisions.

First-Line Agents

Angiotensin-Converting Enzyme Inhibitors

The ACEIs directly inhibit ACE, blocking the conversion of angiotensin I to angiotensin II. This action reduces angiotensin II-mediated vasoconstriction and aldosterone secretion and ultimately lowers BP. Because additional pathways exist for the formation of angiotensin II, ACEIs do not completely block the production of angiotensin II. Aldosterone release is indirectly suppressed by ACEIs; thus, hyperkalemia is possible and potassium concentrations should be monitored. Patients with CKD or volume depletion may be more susceptible to hyperkalemia or to further kidney dysfunction owing to a higher dependence on the vasoconstriction provided by angiotensin II to support GFR among these patients.

Inhibiting ACE also prevents the breakdown and inactivation of bradykinin, which may lead to additive vasodilation by enhancing NO. However, bradykinin accumulation can also cause a nonproductive cough in some patients, which is the most frequent, yet harmless, side effect of ACEI therapy. ACEI therapy has been associated with angioedema, which is a rare, but serious, hypersensitivity reaction. Angioedema typically presents as swelling of the tongue, lips, and mouth, but can also involve the eyes and upper airway.

The development of angioedema requires discontinuation of the ACEI. These agents are metabolically neutral and may have a positive effect on insulin resistance and risk of progression to type 2 diabetes.[27]

Angiotensin Receptor Blockers

The ARBs modulate the RAAS by directly blocking the angiotensin II type 1 receptor site, preventing angiotensin II-mediated vasoconstriction and aldosterone release. Overall, ARBs are the best tolerated of the first-line agents.[28] They do not affect bradykinin and are therefore associated with less incidence of cough. Because aldosterone is indirectly suppressed, monitoring of potassium is important to avoid hyperkalemia. Similar to the ACEIs, patients with CKD or volume depletion may be more susceptible to hyperkalemia or to further kidney dysfunction. These agents are metabolically neutral and may have a positive effect on insulin resistance and risk of progression to type 2 diabetes.[27]

Calcium-Channel Blockers

The CCBs are pharmacologically complex. They reduce calcium entry into smooth muscles, which causes coronary and peripheral vasodilation and lowers BP. All decrease cardiac contractility (except amlodipine and felodipine). Dihydropyridine CCBs are primarily vasodilators that can cause a reflex tachycardia. This is in contrast to the nondihydropyridine CCBs (verapamil and diltiazem) that directly block the atrioventricular (AV) node, decrease heart rate, and decrease cardiac contraction, yet still have vasodilatory effects. Side effects depend on the type of CCB, but can include flushing, peripheral edema, tachycardia, bradycardia or heart block, and constipation.

Thiazide Diuretics

Diuretics, particularly thiazide and thiazide-like (e.g., chlorthalidone) diuretics, have been extensively studied in large landmark clinical trials for hypertension. When initially started, they induce a natriuresis that causes diuresis and decreases plasma volume and CO. With chronic use, diuresis usually dissipates, and CO gradually returns to near-normal levels. The long-term BP-lowering effect in the face of these changes suggests a sustained decrease in PVR as the primary mechanism responsible.

Dose-related electrolyte and metabolic alterations (e.g., hypokalemia, hyperuricemia, hyperglycemia, and hypercholesterolemia) can occur with thiazide diuretics. These effects were particularly problematic when high doses were used many years ago (e.g., hydrochlorothiazide [HCTZ] 100–200 mg/day), but are drastically minimized by using lower doses that are now considered the standard of care (e.g., HCTZ 12.5–25 mg/day).[26] Thiazide diuretics can be used in combination with a potassium- sparing diuretic (i.e., triamterene and amiloride) to minimize potential potassium depletion. Other biochemical changes in glucose and cholesterol are minimal and mostly transient with low-dose therapy.

Second-Line Agents

JNC-8 consensus statement recommends that first-line agents should be used when initiating antihypertensive therapy or when added on to existing antihypertensive therapy unless patients have contraindications to them.[2] In that case, second-line agents may be considered.

β-Blockers

β-Blockers have several direct effects on the CV system. They can decrease cardiac contractility and CO, lower heart rate, blunt sympathetic reflex with exercise, reduce central release of adrenergic substances, inhibit norepinephrine release peripherally, and decrease renin release from the kidney. All these contribute to their antihypertensive effects. Adverse metabolic effects include altered lipids and increased glucose concentrations. Similar to thiazide diuretics, these changes are generally temporary and have minimal to no clinical significance. These agents were considered first line for the treatment of most patients with hypertension in the JNC-7 guideline. However, evidence published after the 2003 JNC-7 has further defined their role.[25] Unless patients have other indication for β-blockers (e.g., CAD or left ventricular dysfunction), they should not be used as first-line agent for primary prevention of CV events in patients with hypertension.

Aldosterone Antagonists

Spironolactone and eplerenone are aldosterone antagonists. Potent blockade of the aldosterone receptor inhibits sodium and water retention and inhibits vasoconstriction. These agents are also considered potassium-sparing diuretics. Hyperkalemia is a known dose-dependent effect with aldosterone antagonists and is more prominent in patients with CKD or in patients taking a concurrent RAAS blocking agent (ACEI, ARB, or direct renin inhibitor). Gynecomastia is a side effect of spironolactone, usually more common with higher doses, that does not occur with eplerenone.

Other Agents

There are other antihypertensive drug classes, many of which are older agents, which should primarily be used to provide additional BP lowering only after first-line and second-line agents have been implemented.

Loop diuretics (e.g., furosemide and torsemide) can be used in some patients for hypertension.[26] When dosed appropriately, they can provide BP reductions similar to those seen with a thiazide diuretic. Because they are short-acting and subject to a significant postdose antinatriuretic effect, they should generally be reserved for patients with heart failure or severe CKD in whom their diuretic action remains prolonged. Significant edema usually accompanies these conditions, such that they generally require a loop diuretic instead of a thiazide diuretic for adequate diuresis and volume removal. Because they are more potent at inducing diuresis compared with thiazide diuretics, they can cause more electrolyte disturbances (e.g., hypokalemia).

Aliskiren, approved in 2007, is the only direct renin inhibitor. Similar to an ACEI or ARB, this agent is a RAAS blocker. It is approved for treatment of hypertension and has been studied in combination with an ACEI, ARB, or thiazide diuretic. It is the newest antihypertensive drug class; therefore, its exact role will continue to evolve as additional clinical data are generated.

α-Blockers (e.g., doxazosin, prazosin, and terazosin) attach to peripheral α_1-receptors, inhibiting the uptake of catecholamines in smooth muscle, and cause vasodilation. Although effective in lowering BP, they have more side effects than first-line or second-line agents. The most prominent side effect is hypotension, which is most evident after the first dose and with postural changes (arising from a lying position to a standing position).

Direct vasodilators (e.g., hydralazine and minoxidil) work on the arterial vasculature. They should be reserved for patients with specific conditions (e.g., severe CKD) or those with very difficult to control BP. Concomitant drug therapy with both a diuretic and an agent that lowers heart rate (a β-blocker, diltiazem, or verapamil) is usually needed to mitigate the associated fluid retention and reflex tachycardia that frequently occur.

Central α_2-agonists (e.g., clonidine and methyldopa) work in the vasomotor centers of the brain where they stimulate inhibitory neurons and decrease sympathetic outflow from the CNS. The resultant decrease in PVR and CO lowers BP. These agents commonly cause anticholinergic side effects (e.g., sedation, dizziness, dry mouth, and fatigue) and possibly sexual dysfunction. Although α_2-agonists lower BP, they often cause fluid retention and should be used in combination with a diuretic.

Adrenergic antagonists (e.g., reserpine, guanadrel, and guanethidine) are not frequently used to treat hypertension. Reserpine depletes catecholamines from storage granules to then decrease BP. High doses are associated with more side effects, but low-dose reserpine (0.05–0.1 mg/day), when used as an additive therapy, is well tolerated. Because of the potential for fluid retention, reserpine requires concurrent diuretic therapy. Guanadrel and guanethidine have numerous significant adverse effects and should be avoided.

CLINICAL EVALUATION

Patient Presentation

CASE 9-1

QUESTION 1: D.C. is a 44-year-old black man who presents to his primary care provider concerned about high BP. At an employee health screening last month, he was told he had hypertension. His medical history is significant for allergic rhinitis. His BP was 144/84 and 146/86 mm Hg last year during an employee health screening at work. D.C.'s father had hypertension and died of an MI at age 54. His mother had diabetes and hypertension and died of a stroke at age 68. D.C. smokes one pack per day of cigarettes and thinks his BP is high because of job-related stress. He does not believe that he really has hypertension. D.C. does not engage in any regular exercise and does not restrict his diet in any way, although he knows he should lose weight.

Physical examination shows he is 175 cm tall, weighs 108 kg (body mass index [BMI] 35.2 kg/m^2), BP is 148/88 mm Hg (left arm) and 146/86 mm Hg (right arm) while sitting, and heart rate is 80 beats/minute. Six months ago, his BP values were 152/88 mm Hg and 150/84 mm Hg when he was seen by his primary care provider for allergic rhinitis. Funduscopic examination reveals mild arterial narrowing and arteriovenous nicking, with no exudates or hemorrhages. The other physical examination findings are essentially normal.

D.C.'s fasting laboratory serum values are as follows:

Blood urea nitrogen (BUN), 24 mg/dL
Creatinine, 1.0 mg/dL
Glucose, 105 mg/dL
Potassium, 4.4 mEq/L
Uric acid, 6.5 mg/dL
Total cholesterol, 196 mg/dL
Low-density lipoprotein cholesterol (LDL-C), 141 mg/dL
High-density lipoprotein cholesterol (HDL-C), 32 mg/dL
Triglycerides, 170 mg/dL

An electrocardiogram (ECG) is normal except for left ventricular hypertrophy (LVH). Why does D.C. have hypertension?

D.C. has hypertension. He has had elevated BP values, measured in clinical environments, and meets the diagnostic criteria for hypertension because two or more of his BP measurements are elevated on separate days.

CASE 9-1, QUESTION 2: What is the proper assessment of D.C.'s BP?

D.C. has essential hypertension; therefore the exact cause is not known. He has several characteristics (e.g., family history of hypertension and obesity) that may have increased his chance of developing hypertension. Race and sex also influence the prevalence of hypertension. Across all age groups, blacks have a higher prevalence of hypertension than do whites and Hispanics.[1] Similar to other forms of CV disease, hypertension is more severe, more likely to include hypertension-associated complications, and occurs at an earlier age in black patients.

Patient Evaluation and Risk Assessment

The presence or absence of hypertension-associated complications as well as other major CV risk factors (Table 9-4) must be assessed in D.C. Also, secondary causes of hypertension (Table 9-2), if suggested by history and clinical examination findings, should be identified and managed accordingly. The presence of concomitant medical conditions (e.g., diabetes) should be assessed, and lifestyle habits should be evaluated so that they can be used to guide therapy.

HYPERTENSION-ASSOCIATED COMPLICATIONS

CASE 9-1, QUESTION 3: Which hypertension-associated complications are present in D.C.?

A complete physical examination to evaluate hypertension-associated complications includes examination of the optic fundi; auscultation for carotid, abdominal, and femoral bruits; palpation of the thyroid gland; heart and lung examination; abdominal examination for enlarged kidney, masses, and abnormal aortic pulsation; lower extremity palpation for edema and pulses; and neurologic assessment. Routine laboratory assessment after diagnosis should include the following: ECG; urinalysis; fasting glucose; hematocrit; serum potassium, creatinine, and calcium; and a fasting lipid panel. Optional testing may include measurement of urinary albumin excretion or albumin-to-creatinine ratio, or additional tests specific for secondary causes if suspected.

D.C. does not yet have hypertension-associated complications. He is exhibiting early signs, however, based on his physical examination that, if left untreated, will likely develop into such complications. These early signs have likely evolved from his longstanding, poorly controlled hypertension. D.C.'s ECG revealed LVH, indicating early cardiac damage. Although the gold standard for confirming LVH is echocardiography, this confirmatory procedure is not necessary unless symptoms are present indicating that LVH has progressed to left ventricular dysfunction (e.g., peripheral edema and shortness of breath). His funduscopic examination reveals mild arterial narrowing and arteriovenous nicking, which are early signs of retinopathy and atherosclerosis. D.C.'s serum creatinine is normal, ruling out overt CKD. Additional testing for microalbuminuria is needed, however, to confirm that he does not have early stage kidney disease.

CASE 9-1, QUESTION 4: What other forms of hypertension-associated complications is D.C. at risk for?

Hypertension adversely affects many organ systems, including the heart, brain, kidneys, peripheral circulation, and eyes. These are summarized in Table 9-4. Damage to these systems resulting from hypertension is termed hypertension-associated complications, target-organ damage, or CV disease. There are often misconceptions about the terms CV disease and CAD. CV disease encompasses the broad scope of all forms of hypertension-associated complications. CAD is simply a subset of CV disease and refers specifically to disease related to the coronary vasculature, including ischemic heart disease and MI. Hypertension-associated complications and major risk factors for developing such complications should be assessed by a thorough patient history, a complete physical examination, and laboratory evaluation.

Hypertension can affect the heart either indirectly, by promoting atherosclerotic changes, or directly, via pressure-related effects. Hypertension can promote CV disease and increase the risk for ischemic events, such as angina and MI. Antihypertensive therapy has been shown to reduce the risk of these coronary events. Hypertension also promotes the development of LVH, which is a myocardial (cellular) change, not an arterial change. These two conditions often coexist, however. It is commonly believed that LVH is a compensatory mechanism of the heart in response to the increased resistance caused by elevated BP. LVH is a strong and independent risk factor for CAD, left

ventricular dysfunction, and arrhythmia. LVH does not indicate the presence of left ventricular dysfunction, but is a risk for progression to left ventricular dysfunction, which is considered a hypertension-associated complication. This may be caused by ischemia, excessive LVH, or pressure overload. Ultimately, left ventricular dysfunction results in a decreased ability to contract (systolic dysfunction).

Hypertension is one of the most frequent causes of cerebrovascular disease. Cerebrovascular signs can manifest as transient ischemic attacks, ischemic strokes, multiple cerebral infarcts, and hemorrhages. Residual functional deficits caused by stroke are among the most devastating forms of hypertension-associated complications. Clinical trials have demonstrated that antihypertensive therapy can significantly reduce the risk of both initial and recurrent stroke. A sudden, prolonged increase in BP can also cause hypertensive encephalopathy, which is classified as a hypertensive emergency.

The GFR is used to estimate kidney function, which declines with aging. This rate of decline is greatly accelerated by hypertension. Hypertension is associated with nephrosclerosis, which is caused by increased intraglomerular pressure. CKD, whether mild or severe, can progress to kidney failure (stage 5 CKD) and the need for dialysis. Studies have demonstrated that controlling hypertension is the most important strategy to slow the rate of kidney function decline,[29] but it may not be entirely effective in slowing the progression of renal impairment in all patients.

CKD is staged based on estimated GFR values.[30] Stage 3 CKD (moderate) is defined as a GFR 30 to 59 mL/minute/1.73 m^2, stage 4 CKD (severe) is 15 to 29 mL/minute/1.73 m^2, and stage 5 (kidney failure) is less than 15 mL/minute/1.73 m^2 or the requirement of dialysis. In hypertension, stage 3 CKD or worse is considered a hypertension-associated complication. An estimated GFR of less than 60 mL/minute/1.73 m^2 corresponds approximately to a serum creatinine concentration of greater than 1.5 mg/dL in an average man and greater than 1.3 mg/dL in an average woman. The presence of persistent albuminuria (>300 mg albumin in a 24-hour urine collection or 200 mg albumin/g creatinine on a spot urine measurement) also indicates significant CKD. (Note: These definitions of the stages of kidney disease and albuminuria will be used throughout the remaining cases in this chapter.) Assessment of kidney function is discussed in Chapter 2, Interpretation of Clinical Laboratory Tests, and Chapter 28, Chronic Kidney Disease.

Peripheral arterial disease, a noncoronary form of atherosclerotic vascular disease, is considered a hypertension-associated complication. It is equivalent in CV risk to CHD.[3] Risk factor reduction, BP control, and antiplatelet agent(s) are needed to decrease progression. Complications of peripheral arterial disease can include infection and necrosis, which in some cases require revascularization procedures or extremity amputation.

Hypertension causes retinopathies that can progress to blindness. Retinopathy is evaluated according to the Keith, Wagener, and Barker funduscopic classification system. Grade 1 is characterized by narrowing of the arterial diameter, indicating vasoconstriction. Arteriovenous nicking is the hallmark of grade 2, indicating atherosclerosis. Longstanding, untreated hypertension can cause cotton wool exudates and flame hemorrhages (grade 3). In severe cases (e.g., hypertensive emergency) papilledema occurs, and this is classified as grade 4.

MAJOR RISK FACTORS

CASE 9-1, QUESTION 5: Which major CV risk factors are present in D.C.?

Hypertension is one of nine major CV risk factors (Table 9-4). These are not risk factors for developing hypertension; rather, they increase the risk of hypertension-associated complications. D.C. has multiple CV risk factors: smoking, dyslipidemia, family history of premature CHD in a first-degree relative (father), hypertension, obesity, and physical inactivity.

D.C. is a primary prevention patient because he does not yet have any hypertension-associated complications. He has multiple major CV risk factors, so controlling his BP is of paramount importance to reduce the risk of developing hypertension-associated complications. The JNC-8 guidelines, considered the gold standard for treatment, recommend a BP goal of less than 140/90 mm Hg for D.C. because he is a primary prevention patient less than 60 years of age.

Many of D.C.’s risk factors are modifiable. He is a smoker and this significantly increases his CV risk and may reduce the efficacy of antihypertensive therapy. Smoking cessation may not independently lower D.C.’s BP, but it will decrease his overall risk of CV disease (see Chapter 91, Tobacco Use and Dependence). D.C. is obese based on his BMI. His lack of physical activity and dietary patterns have likely contributed to his obesity. A more focused patient interview on diet and exercise would be helpful to reinforce the assumption that he has a sedentary lifestyle. D.C.’s dyslipidemia increases his CV risk, and lipid-lowering therapy should be considered to further decrease the risk of CV disease (see Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease).[31]

Advanced age is considered a major CV risk factor. Although CHD in the elderly is not considered premature, increasing age increases the risk of hypertension-associated complications. Premenopausal women are at low risk for CV disease. However, CV risk in women increases significantly after menopause, similar to the increased risk in men. Therefore, cutoff values for age as a risk factor in men and women are separated by 10 years (>55 years for men, >65 years for women). At age 50, D.C. does not yet have this risk factor.

CASE 9-1, QUESTION 6: What is D.C.'s BP goal?

The overarching goal of treating hypertension is to lower hypertension-associated complications. Control of BP is the most feasible clinical end point to guide therapy and should be viewed as a surrogate for attaining this goal. D.C.'s goal BP is less than 140/90 mm Hg according to JNC-8.

PRINCIPLES OF TREATMENT

Goals of Therapy

CASE 9-1, QUESTION 7: What are the goals of treating D.C.?

Pharmacotherapy principles to achieve these goals include selecting a treatment regimen with antihypertensive agent(s) that reduces risk of CV events, complemented by appropriate lifestyle modifications (Table 9-5).

Health Beliefs and Patient Education

CASE 9-1, QUESTION 8: What patient education should be provided to D.C. regarding his hypertension?

Patient education is needed to ensure that D.C. understands his disease and its complications (Table 9-6). This should comprehensively include information on disease, treatment, adherence, and complications. Several approaches can be effective, but all methods should include direct communication between the clinician and the patient. Multidisciplinary approaches to disease-state management in hypertension can effectively use a team of different clinicians (e.g., physicians, nurse practitioners, physician assistants, and pharmacists). Providing face-to-face education is most common, but the key components in patient education can be delivered via indirect interactions (e.g., telephone).

Table 9-6

Patient–Provider Interactions for Hypertension

Patient Education

- Assess patient’s understanding and acceptance of the diagnosis of hypertension
- Discuss patient’s concerns and clarify misunderstandings
- When measuring BP, inform the patient of the reading both verbally and in writing
- Assure patient understands his or her goal BP value
- Ask patient to rate (1–10) his or her chance of staying on treatment
- Inform patient about recommended treatment, including lifestyle modification. Provide specific written information using standard brochures when available
- Elicit concerns and questions and provide opportunities for patient to state specific behaviors to carry out treatment recommendations
- Emphasize
  - the need to continue treatment
  - that control does not mean cure
  - that elevated BP is usually not accompanied by symptoms

Individualize Treatment Regimens

- Include the patient in decision making
- Simplify the regimen to once-daily dosing, whenever possible
- Incorporate treatment into patient’s daily lifestyle
- Set realistic short-term objectives for specific components of the medication and lifestyle modification plan
- Encourage discussion of diet and physical activity, adverse drug effects, and concerns
- Encourage self-monitoring with validated BP devices
- Minimize the cost of therapy, when possible
- Discuss adherence at each clinical encounter
- Encourage gradual sustained weight loss

BP, blood pressure

Education should be tailored to the patient’s specific needs. For example, some patients are able to comprehend the importance of achieving controlled BP by reading written materials, whereas others understand this only after implementing self-BP monitoring. The patient education process must be continuous throughout the duration of therapy. Not all aspects need to be discussed during each clinical interaction. Careful selection of both written and verbal information should be considered so that patients are not overwhelmed or intimidated. National Heart, Lung, and Blood Institute patient education materials are available at http://www.nhlbi.nih.gov/health/public/heart/index.htm#hbp. It is important that clinicians review all materials provided to patients to identify the source of information, assess ease of reading, and identify omitted information and sources of confusion or anxiety (e.g., drug side effects).

Patients such as D.C. often incorrectly explain BP elevation as stress related. Although certain patients (e.g., those with white-coat hypertension) may have BP that is more highly reactive, most patients with essential hypertension will have an elevated BP regardless of their stress level. D.C. should be informed about the cause of his disease and the lack of correlation between stress or symptoms and high BP. Importantly, D.C. needs to realize that elevated BP is almost always asymptomatic and that it can cause serious long-term complications. It is essential that he understand the chronic nature of hypertension and the need for long-term therapy. Otherwise, he may adhere to his treatment only when he "feels his BP is high" or during stressful events.

Some patients believe they can control their BP by stress management rather than with antihypertensive drug therapy and lifestyle modifications. Controlled trials have not consistently proven that stress management is beneficial in treating hypertension.[32] It is important to determine the patient's health beliefs and attitudes and to provide education about the etiology and management of hypertension to promote BP control.

Another common myth patients believe is that treating hypertension commonly leads to fatigue, lethargy, and sexual dysfunction. This misconception can compromise adherence and be a limiting factor in appropriate management. Clinical trials have repeatedly reported that quality of life is better with active medication than with placebo.[33–36] Data have indicated that as many as 27% of men with hypertension have erectile dysfunction.[5] Although many patients believe this to be a medication-related side effect and that incidence rates vary among antihypertensive agents and classes, erectile dysfunction is likely caused by penile arterial changes (probably atherosclerosis), which is related to uncontrolled or untreated hypertension.[37]

Benefits of Treatment

CASE 9-1, QUESTION 9: How can antihypertensive drug therapy reduce D.C.'s risk of hypertension-associated complications?

Without a doubt, antihypertensive therapy reduces the risk of CV disease and CV events in patients with hypertension. Numerous landmark placebo-controlled studies have clearly demonstrated these benefits. The first large-scale trial, published in 1967, was the Veterans Administration (VA) study in men with DBP between 115 and 129 mm Hg.[38] This study was prematurely stopped because benefits of treatment were so dramatic. Antihypertensive therapy significantly reduced cerebral hemorrhage, MI, left ventricular dysfunction, retinopathy, and kidney disease. Other landmark placebo-controlled studies have evaluated antihypertensive therapy in patients with less severe hypertension and have shown a reduced risk of CV events (stroke, ischemic heart disease, and left ventricular dysfunction) and even CV death.[29,31,39,40] Placebo-controlled studies evaluating morbidity and mortality in hypertension are now not only unnecessary, but considered unethical because of the well-established benefits of treatment. Even small reductions in BP have been associated with significant CV benefits. Based on prospective observational studies, a persistent 5 mm Hg reduction in DBP is associated with a 21% reduction in CHD and a 34% reduction in stroke.[41,42]

Most antihypertensive drugs reduce LVH through varying mechanisms. It is logical that regression of LVH is desirable, but this remains unproved.

CASE 9-1, QUESTION 10: Will D.C.'s early signs of hypertension-associated complications improve or reverse with appropriate BP control?

Reductions in BP can reverse many of the changes associated with D.C.'s retinopathy. Studies have demonstrated that the risk of retinopathy in diabetes increases significantly when BP is elevated and that BP lowering can slow this progression. Although D.C. has an elevated fasting glucose, he does not have diabetes. Regardless, lowering BP is desirable for anticipated beneficial effects on his retinopathy.

HYPERTENSION MANAGEMENT

Lifestyle Modifications

CASE 9-1, QUESTION 11: Should D.C. start antihypertensive drug therapy, or are lifestyle modifications alone sufficient?

It is reasonable to assume that lifestyle modifications can partially help D.C. achieve his BP goal. D.C. has multiple major CV risk factors and has early evidence of hypertension-associated complications. Lifestyle modifications are germane to the appropriate treatment of hypertension, but prospective clinical trials have not proven that this treatment approach prevents CV disease in patients with hypertension similar to what is proven antihypertensive drug therapy. Hence, initiation of drug therapy should not be delayed unnecessarily, especially for patients with CV risk factors.

MODALITIES THAT LOWER BP

CASE 9-1, QUESTION 12: Which lifestyle modifications can D.C. implement to lower his BP?

Weight reduction through dietary modifications and physical activity and sodium restriction are the most apparent lifestyle modifications for D.C. to lower his BP. A thorough patient interview (diet history to quantify total calories, sodium, fat, and cholesterol, and social history to determine alcohol consumption and confirm cigarette use) should be obtained. Based on this interview, customized recommendations can be made.

The DASH diet should be strongly encouraged in D.C. based on proven benefits.[23]

D.C.'s BMI of 30 kg/m^2 or more classifies him as obese. As little as a 5% to 10% loss in weight (5–11 kg) will provide global health benefits. Strategies that increase his aerobic activity, in addition to diet, can augment weight loss.

OTHER CARDIOVASCULAR RISK-REDUCTION STRATEGIES

CASE 9-1, QUESTION 13: Aside from treating hypertension, which other CV risk reduction strategies should be recommended in D.C.?

Smoking Cessation

Smoking is an important modifiable major CV risk factor. Cigarette smoking has been shown to independently increase CV and overall mortality, and cessation can decrease the incidence of CV disease.[43] Although smoking does not chronically lower BP, smoking cessation is strongly recommended to improve overall health. Hypertensive smokers should be continually educated about the risks associated with cigarette smoking and directed to behavior-modification programs that can assist smoking cessation efforts (see Chapter 91, Tobacco Use and Dependence).

Low-Dose Aspirin

Low-dose aspirin therapy (81 mg daily) is recommended by the US Preventive Services Task Force (USPSTF) for the primary prevention of MI in certain men 45 to79 years old and ischemic stroke in certain women 55 to 79 years old.[44] This recommendation is contingent on age and quantitative risk of CHD in men (e.g., Framingham risk scoring) and ischemic stroke in women. D.C. is not yet a candidate for low-dose aspirin based on his age.

Controlling Other Comorbid Diseases

In addition to treating hypertension and lowering BP to goal, controlling other comorbidities, which are themselves associated with increased CV risk, should be performed. When present, dyslipidemia, diabetes mellitus, obesity, and any other forms of CV disease should be diligently treated and controlled. D.C. has dyslipidemia and requires statin treatment (individuals without clinical atherosclerotic cardiovascular disease [ASCVD] or diabetes, who are 40–75 years of age with LDL-C 70–189 mg/dL, and have an estimated 10-year ASCVD risk of 7.5% or higher—D.C's calculated risk is 9.6%), and his CV risk would be reduced with better control of this condition (see Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease).

Pharmacotherapy for Primary Prevention Patients

EVIDENCE-BASED RECOMMENDATIONS

CASE 9-1, QUESTION 14: Which treatment principles need to be considered when choosing an initial antihypertensive agent for D.C.?

Selecting an antihypertensive drug is complex. There are numerous choices, and all agents can effectively lower BP. Depending on the dose used, BP reductions are similar.[45] BP reduction, however, is only a surrogate end point of therapy and does not necessarily reflect overall effectiveness. Reducing hypertension-associated complications is the ultimate goal of treatment.

CASE 9-1, QUESTION 15: Which antihypertensive agents are appropriate first-line treatments for D.C.?

The JNC-8 report from 2013 outlines evidence-based pharmacotherapy recommendations accumulated from more than 50 years of clinical trials.[2] Because D.C. is black and does not have CKD, JNC-8 recommends thiazide-like diuretics or CCBs as first-choice antihypertensive therapy. This recommendation is based on the propensity of data showing reduced morbidity and mortality with these drug classes.[46]

Traditional landmark placebo-controlled hypertension studies (e.g., the SHEP,[39] Swedish Trial of Old Patients with Hypertension,[31] and Medical Research Council[29]) established that treating hypertension produces significant reductions in CV events (e.g., stroke and MI) and mortality. These traditional landmark trials used thiazide diuretic-based therapy, and thus thiazide diuretics have been the quintessential antihypertensive agent for most patients. Subsequently, several clinical trials evaluating newer agents (ACEI, ARB, and CCB) have provided additional evidence on CV event reduction.[12,40,47–67] Most of these trials do not include a placebo group (because it is unethical to use placebo in long-term studies); rather, they use an active antihypertensive agent as the comparator (often a thiazide diuretic or β-blocker or both). In those studies in which newer antihypertensive agents were compared with thiazide diuretics, very similar effects were seen. One of these studies was the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT).[48] In the ALLHAT, 33,357 patients with hypertension were randomly assigned in double-blind manner to thiazide diuretic (chlorthalidone), CCB (amlodipine), or ACEI (lisinopril)-based therapy. After a mean follow-up to 4.9 years, the incidence of the primary end point of fatal CHD or nonfatal MI was similar among all three treatment arms.

CASE 9-1, QUESTION 16: Should monotherapy or two-drug therapy be started in D.C. as his initial regimen?

A monotherapy approach is an option for D.C. Monotherapy with a CCB, or thiazide diuretic as recommended by JNC-8, will likely reduce his BP to less than 140/90 mm Hg. If D.C. is not black, ACEI and ARB would also be optimal alternatives.

SPECIAL POPULATIONS

Black Patients

CASE 9-1, QUESTION 17: How should D.C.'s race influence the selection of an antihypertensive regimen?

As monotherapy, it is well documented that a thiazide diuretic or a CCB is highly effective in lowering BP in black patients. This is likely because of the profile of low renin coupled with high plasma volume pattern of hypertension that is commonly seen in black patients with hypertension. Conversely, ACEI, ARB, or β-blocker monotherapy is less effective in lowering BP in blacks compared with white patients. However, when these agents are used in combination, especially with a thiazide diuretic, these race-based differences seen in BP lowering with monotherapy are abolished. This information may aid in selecting one drug option over another in a primary prevention patient, but does not apply to black patients with other comorbidities, in whom choice of therapy follows an evidence-based approach to selection based on the comorbidities.

D.C. does not have any other comorbidities for specific antihypertensive drug therapy. His first-line treatment option is CCB or thiazide diuretic. Monotherapy with either a thiazide diuretic or a CCB would be very effective in BP lowering; either of these two drugs is an acceptable treatment option for him.

Very Elderly Patients

CASE 9-2

QUESTION 1: B.D is an 83-year-old woman with a past medical history of hypertension, osteoporosis, and hypothyroidism. Her present medications are levothyroxine 100 mcg daily, alendronate 70 mg weekly, vitamin D 800 international units daily, and calcium carbonate 600 mg twice daily. She has been diagnosed with hypertension for 2 years, and it has been treated with lifestyle modifications (sodium restriction and exercise 3 times weekly). B.D. is 64 inches tall and weighs 55 kg. Her current BP is 160/78 mm Hg (160/80 mm Hg when repeated). All serum laboratory tests are normal. Her provider has been reluctant to start antihypertensive drug therapy because of B.D.'s age. How is treatment of B.D.'s hypertension different from that of a younger patient?

Older patients with hypertension (>65 years of age) have the lowest rates of BP control, and this rate decreases in even older populations.[1] Very elderly patients like

B.D., similar to black patients, respond best to thiazides and CCBs and less to ACEIs, ARBs, and β-blockers when these are used as monotherapy. However, it is unclear whether these small differences in BP lowering among classes are clinically significant; thus they are all recommended as first choice per JNC-8 guidelines.

Isolated Systolic Hypertension

B.D. has isolated systolic hypertension (ISH), which is defined as an elevated SBP with a normal DBP.[2] This pattern of hypertension is most common in older patients and incurs a significant risk for CV disease. It was once thought that patients with ISH required high SBP to ensure normal perfusion of the heart and brain and that treating ISH would further lower DBP and worsen organ perfusion. Evidence clearly demonstrates, however, that treating ISH with antihypertensive drug therapy reduces the risk of CV events.[31,39,54] B.D.'s hypertension should be managed with drug therapy in addition to lifestyle modifications.

CASE 9-2, QUESTION 2: What data support antihypertensive drug therapy in patients who are very elderly, similar to B.D.?

The care of patients with ISH, including the very elderly, should follow the same general hypertension care principles that apply to all patients, with two exceptions. The first is that the BP goal is different. JNC-8 guideline recommends that BP goal of patients 60 years or older be <150/90 mm Hg.[2] Unless they also have CKD and are aged < 70 years, their BP goal would be similar to younger patient population, < 140/90 mm Hg. The second exception is that lower doses should be used when first starting therapy because of higher risk of developing orthostatic hypotension. Orthostatic hypotension occurs when standing upright results in an SBP decrease of more than 20 mm Hg (or a DBP decrease of more than 10 mm Hg) after 3 minutes of standing and is often accompanied by dizziness or fainting. This is a risk of rapid BP lowering. Orthostatic hypotension is more frequent in elderly patients (especially those with ISH), diabetes, autonomic dysfunction, volume depletion, and in patients taking certain drugs (i.e., diuretics, nitrates, α-blockers, psychotropic agents, and phosphodiesterase inhibitors). Antihypertensive dose increases should be gradual to minimize the risk of hypotension. Moreover, initial therapy with two drugs should probably be avoided in the elderly (age 80 years or older) owing to the increased risk of orthostatic hypotension.

The very elderly (i.e., patients 80 years or older) have traditionally been underrepresented in landmark placebo-controlled clinical trials. However, the HYVET was a placebo-controlled, randomized trial evaluating the effect of antihypertensive pharmacotherapy (ACEI with or without a thiazide-like diuretic) in patients with hypertension aged 80 years and older.[20] This trial was stopped prematurely, after 1.8 median years, owing to a significant reduction in overall mortality in the treatment arm. The HYVET provides compelling evidence that treatment of hypertension in the very elderly provides significant benefits. B.D.

should be started on a low-dose thiazide diuretic or CCB for the treatment of her hypertension. For elderly patients with existing incontinence, diuretic therapy will be problematic. Under this circumstance, a CCB would be a more reasonable first-line option. Considering her advanced age, starting with monotherapy is appropriate to reduce her risk of orthostatic hypotension.

ADDITIONAL CONSIDERATIONS

CASE 9-3

QUESTION 1: You are developing a collaborative drug therapy management (CDTM) protocol for treatment of hypertension that will be used by clinical pharmacists. In your CDTM protocol, you include multiple pharmacotherapy options (ACEIs, ARBs, CCBs, and thiazide diuretics) as equally recommended in primary prevention patients. However, you wish to include additional guidance on how to select an individual drug class to treat hypertension. What additional factors should be considered in your protocol when selecting a first-line agent for a specific primary prevention patient?

It cannot be emphasized enough that selecting pharmacotherapy should follow an evidence-based philosophy. In patients with other comorbidities, certain antihypertensive drug classes are recommended in place of other options. In patients without other comorbidities, factors such as concomitant diseases, medication costs, serum electrolytes, and prior medication intolerances should be considered (Table 9-7). These are helpful when selecting initial therapy for a primary prevention patient who has more than one acceptable drug class as a first-line option or when selecting add-on therapy to further lower BP. These are discussed later in this chapter.

Table 9-7

Additional Considerations in Antihypertensive Drug Choice[a]

Antihypertensive Agent	Situations With Potentially Favorable Effects	Situations With Potentially Unfavorable Effects[b]	Avoid Use
ACEI	Low-normal potassium, elevated fasting glucose, microalbuminuria (with or without diabetes)	High-normal potassium or hyperkalemia	Pregnancy, bilateral renal artery stenosis, history of angioedema
ARB	Low-normal potassium, elevated fasting glucose, microalbuminuria (with or without diabetes)	High-normal potassium or hyperkalemia	Pregnancy, bilateral renal artery stenosis
CCB: dihydropyridine	Raynaud phenomenon, elderly patients with isolated systolic	Peripheral edema, left ventricular dysfunction (all except amlodipine and	

	hypertension, cyclosporine-induced hypertension	felodipine), high-normal heart rate or tachycardia	
CCB: nondihydropyridine	Raynaud phenomenon, migraine headache, supraventricular arrhythmias, high-normal heart rate or tachycardia	Peripheral edema, low-normal heart rate	Second- or third-degree heart block, left ventricular dysfunction
Thiazide diuretic	Osteoporosis or at increased risk for osteoporosis, high-normal potassium	Gout, hyponatremia, elevated fasting glucose (as monotherapy), low-normal potassium or sodium	

High-normal refers to patients in the high end of the normal range, but not above the range.

Low-normal refers to patients in the low end of the normal range, but not below the range.

[a]These considerations should never replace drug recommendations for a compelling indication.

[b]May use but requires diligent monitoring.

ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin II receptor blocker; CCB, calcium-channel blocker.

The costs of treating hypertension and related complications are substantial to patients and health systems.[68] With expanding availability of generic agents, costs attributed to drug acquisition are small in comparison with expenses for laboratory evaluations, office visits, and medical care for hypertension-associated complications. Whenever possible, affordable regimens that do not compromise efficacy should be designed. Generic antihypertensive products are equally effective and less expensive than brand-name products, and all first- and second-line antihypertensive classes have generic alternatives. The frequency of administration can influence treatment. Once-daily administration assists adherence; all major drug classes contain agents that are either naturally long-acting or formulated in long-acting preparations.

Pharmacotherapy for Patients with Other Comorbidities

CASE 9-3, QUESTION 2: In your CDTM protocol, when should an ACEI or ARB be identified as first-line therapy ahead of other antihypertensive agents?

Unlike previous editions of JNC guidelines, JNC-8 guidelines did not specifically discuss how hypertension treatment should be managed in patients with other comorbidities (besides diabetes and CKD). However, there are other coexisting diseases or hypertension-associated complications in patients which may warrant the use of certain classes of antihypertensive because these agents show significant benefits in reducing CV morbidity or mortality in patients with those specific comorbidities.

DIABETES

Kidney disease and CV disease are both long-term hypertension-associated complications that are at high risk of occurring in patients with diabetes. JNC-8 recommends the same four classes of antihypertensive agents as first choice in nonblack patients with diabetes for primary prevention of CV events (ACEI, ARB, CCB, and thiazide diuretics) and thiazide diuretics and CCB in black patients.[2] When compared head to head, ACEIs are superior to dihydropyridine CCBs at reducing CV events.[57,58] Subgroup analyses of larger clinical trials further support CV event reduction with ACEIs and ARBs. Therefore, ACEI and ARB may be preferred initial antihypertensive therapy for a patient with diabetes if there is no other contraindication.

CASE 9-3, QUESTION 3: In your CDTM protocol, how should significant CKD be defined so that patients with CKD can be identified and treated appropriately?

CHRONIC KIDNEY DISEASE

It is common that CKD presents initially with microalbuminuria (30–299 mg albumin in a 24-hour urine collection) that can progress over the course of several years to overt kidney failure.[30] Progression is accelerated in the presence of both hypertension and diabetes. JNC-8 recommends ACEI or ARB therapy to be used as first-line therapy in CKD patients because both have been shown to reduce the progression of CKD in type 1 diabetes,[69] in type 2 diabetes,[61,62] and in those without diabetes.[65,70] Recently, ARB therapy has also been shown to decrease risk of developing microalbuminuria in patients with diabetes.[71]

Although many of the long-term benefits of ACEI or ARB therapy may be from BP lowering, their evidence base is robust enough to support their first-line use in CKD.[72,73] After ACEI or ARB therapy has been implemented, data support a CCB as the second drug because this has been shown to reduce progression of CKD better than a thiazide diuretic as the second drug added based on the Avoiding Cardiovascular Events through Combination Therapy in Patients Living with Systolic Hypertension (ACCOMPLISH) trial.[74]

CASE 9-3, QUESTION 4: In your CDTM protocol, although β-blocker is no longer considered as a first choice for primary prevention, are there any cases when β-blocker therapy would be identified as an appropriate first-line antihypertensive drug therapy?

CHRONIC AND ACUTE CORONARY ARTERY DISEASE

The American College of Cardiology (ACC)/AHA have guidelines for chronic CAD that recommend treatment with a β-blocker, followed shortly thereafter by the addition of an ACEI.[75] β-Blockers (those without intrinsic sympathomimetic activity [ISA]) decrease the risk of a subsequent MI or sudden cardiac death by decreasing the adrenergic burden on the heart, and progression of coronary atherosclerosis. ACEI therapy promotes cardiac remodeling, improves cardiac function, and reduces the risk of CV events. An ARB is an alternative in patients who do not tolerate an ACEI, because fewer data exist that assess the long-term impact of an ARB on CV events compared with an ACEI in chronic CAD.[76,77] A thiazide diuretic can be added to the core regimen of a β-blocker with an ACEI (or ARB) if additional BP reduction is needed. However, if an additional agent is needed to treat ischemic symptoms for patients with chronic stable angina, a dihydropyridine CCB can be added to this core regimen. If a β-blocker cannot be used because of intolerance or contraindication, a nondihydropyridine CCB can be used as an alternative to a β-blocker. Acute CAD, also called acute coronary syndrome, includes unstable angina, non–ST-segment elevation MI, and ST-segment elevation MI. The ACC/AHA guidelines for these conditions indicate a β-blocker as first-line pharmacotherapy.[78,79]

LEFT VENTRICULAR DYSFUNCTION

Pharmacotherapy for left ventricular dysfunction should include a three-drug combination of an ACEI, a β-blocker, and an aldosterone antagonist, plus loop diuretics depending on the need for diuresis.[79] ACEIs, β-blocker, and aldosterone antagonists, all have numerous landmark clinical trials showing reduced morbidity and mortality rates, whereas diuretics provide primarily symptomatic relief of edema.[79]

According to evidence-based medicine principles, only metoprolol, carvedilol, and bisoprolol are indicated for left ventricular dysfunction. Other β-blockers (e.g., atenolol) should not be used in patients with left ventricular dysfunction because they do not have supporting data demonstrating they reduce CV event rates in these patients. Patients should be clinically euvolemic and hemodynamically stable before adding a β-blocker. As discussed in Chapter 14 (Heart Failure), it is important to start with very low doses of a β-blocker, then slowly titrate upward over the course of several weeks to the recommended dosing range for left ventricular dysfunction. An ARB can be used as an alternative to an ACEI.[79]

Potassium serum concentrations must be carefully monitored in the situation when ACEI (or ARB) and aldosterone antagonist are used together. Alternatively, the combination of hydralazine with isosorbide dinitrate can be added in black patients.[80] This combination has been demonstrated to improve CV outcome in this patient population.

Monitoring Therapy

Four aspects of treatment must always be considered: (a) BP response to attain goal, (b) adherence with lifestyle modifications and pharmacotherapy, (c) progression to hypertension-associated complications, and (d) drug-related toxicity.

Reduction in BP should be evaluated 1 to 4 weeks after starting or modifying therapy for most patients. BP usually begins to decrease within 1 to 2 weeks of starting an agent, but steady-state antihypertensive effects can take up to 4 weeks. If patients are in hypertensive crisis, evaluation should occur sooner, within hours to days (see Chapter 16, Hypertensive Crises).

Two BP values separated by at least 1 minute should be measured during each clinical evaluation, with the average used to make a proper assessment. If dehydration or orthostatic hypotension is suspected, BP should be measured in both the seated and standing positions to detect orthostatic changes. For routine monitoring, measuring BP in the seated position is sufficient. Self-BP monitoring values should be considered if available. Normally, however, they are slightly lower (5 mm Hg) than clinical values even in patients without white-coat hypertension. For example, patients with a goal BP value of less than 140/90 mm Hg should have home measurements that are less than 135/85 mm Hg.[7]

All patients should be questioned in a nonthreatening manner regarding adherence with lifestyle modifications and drug therapy. This is especially important for complex regimens, when drug intolerance is likely, or when financial constraints hinder acquisition of medications. Evaluating hypertension-associated complications and drug side effects are essential. New hypertension-associated complications may necessitate changes to treat a compelling indication or attain a new BP goal. Drug-related side effects may similarly require therapy modifications.

CLINICAL SCENARIOS

Diuretics

CASE 9-4

QUESTION 1: B.A. is a 58-year-old woman who is postmenopausal, does not smoke, and never drinks alcohol. Since being diagnosed with hypertension, she has modified her diet, begun routine aerobic exercise, and has lost 10 kg in the past 18 months. She now weighs 72 kg and is 165 cm tall. Her BP is now 150/94 mm Hg (150/92 mm Hg when repeated) and has consistently remained near this value for the past year. Her BP when first diagnosed was 156/96 mm Hg. Physical examination shows no LVH and no retinopathy. Urinalysis is negative for protein. Other laboratory tests are normal, except for dyslipidemia. B.A. has no health insurance and is concerned about the cost of therapy. She takes over-the-counter calcium with vitamin D, and her provider wants to start HCTZ 25 mg/day. Is HCTZ an appropriate agent for B.A.?

B.A. is a primary prevention patient with uncontrolled hypertension. According to the JNC-8, her BP goal is less than 140/90 mm Hg.[2] Initial monotherapy is reasonable. Appropriate first-line treatment options include an ACEI, ARB, CCB, or thiazide diuretic. All of these drug classes have generic options and should be easily affordable for B.A. A thiazide diuretic may also benefit her osteoporosis (Table 9-7) and is an appropriate choice. Several types of diuretics are used to manage hypertension (Table 9-8).[26] All lower BP, with differences being duration of action, potency of diuresis, and electrolyte abnormalities.

THIAZIDES

Thiazides are diuretics of choice for most patients with hypertension. Similar to loop diuretics, an initial diuresis is experienced. After approximately 4 to 6 weeks of thiazide diuretic therapy, diuresis dissipates, however, and is supplanted by a decrease in PVR, which is responsible for sustaining antihypertensive effects.

CASE 9-4, QUESTION 2: How should a thiazide diuretic be started in B.A.?

Table 9-8

Diuretics in Hypertension

Category	Selected Products	Usual Dosage Range (mg/day)	Dosing Frequency
Thiazide and thiazide-like	Chlorthalidone	12.5–25	Daily
	Hydrochlorothiazide	12.5–25	Daily
	Indapamide	1.25–5	Daily
	Metolazone	2.5–10	Daily
	Metolazone	0.5–1.0	Daily
Loop	Bumetanide	0.5–4	BID
	Furosemide	20–80	BID
	Torsemide	2.5–10	Daily
Potassium-sparing	Amiloride	5–10	Daily to BID
	Triamterene	50–100	Daily to BID
Potassium-sparing combination	Triamterene/HCTZ	37.5/25–75/50	Daily
	Spironolactone/HCTZ	25/25–50/50	Daily
	Amiloride/HCTZ	5–10/50–100	Daily
Aldosterone antagonist	Eplerenone	50–100	Daily to BID
	Spironolactone	12.5–50	Daily to BID

BID, 2 times daily; HCTZ, hydrochlorothiazide.

Hydrochlorothiazide Versus Chlorthalidone

HCTZ and chlorthalidone have been used in several major outcome trials, although only chlorthalidone-based regimens have proven to be of benefit in the low doses commonly used in practice today.[29,31,39,48,54,81,82] Both agents are inexpensive and dosed once daily, but HCTZ is most frequently used in the United States and is more widely available in fixed-dose combination products. The usual starting dose of HCTZ or chlorthalidone is 12.5 mg once daily. A maintenance dose of 25 mg once daily can effectively lower BP and has a low incidence of side effects (e.g., hypokalemia and hyperuricemia) that can be managed with routine monitoring.[33,45,46]

Significant controversy surrounds the comparative efficacy of HCTZ and chlorthalidone. Most clinicians, including the AHA, assume a class effect for these two drugs.[10] However, class effects can be legitimized only after assurance of equipotent dosing; for antihypertensives, when they are not directly compared in a CV event trial, it assumes that if two agents achieve similar BP lowering then both achieve similar reduction in CV events. With regard to HCTZ and chlorthalidone, this assumption is unproven. Chlorthalidone is more potent on a milligram per milligram basis and has a longer half-life than HCTZ (50–60 hours vs. 9–10 hours).[83] Based on a comparative study using 24-hour ABPM, it appears that the equipotent dose of chlorthalidone 25 mg daily is HCTZ 50 mg daily, but this dose of HCTZ is unpopular because of increased side effects. Consequently, it is believed by some that the antihypertensive efficacy of chlorthalidone is greater than HCTZ when contemporary doses are used; the 12.5- to 25-mg doses of chlorthalidone do not appear to significantly increase the risk of hypokalemia more so than HCTZ.[84] Complicating this issue is evidence demonstrating that office BP tends to overestimate the response to HCTZ, and the 24-hour BP lowering with HCTZ is only comparable to other common agents (ACEI, ARB, CCB, and even β-blocker) when 50 mg daily is used.[85] Recently, data from the Multiple Risk Factor Intervention Trial indicate that chlorthalidone reduces CV events more than HCTZ.[86] Although chlorthalidone is the most optimal and evidence-based thiazide diuretic for B.A., HCTZ remains currently accepted in the clinical environment as a reasonable thiazide diuretic for hypertension assuming her BP goal can be readily achieved with its use.

LOOP DIURETICS

Loop diuretics produce a more potent diuresis, but a smaller decrease in PVR, and less vasodilation than thiazide diuretics. They are subject to a significant postdose antinatriuretic period, which offsets their antihypertensive effect. Therefore, a thiazide is more effective at lowering BP than loop diuretics in most patients. Loop diuretics are usually considered only for patients with severe CKD (estimated GFR <30 mL/minute/1.73 m^2), left ventricular dysfunction, or severe edema. In these patients, potent diuresis is often needed. Furosemide has a short duration of effect and should be given twice daily when used in hypertension, whereas torsemide has a longer duration of action and can be given once daily.

POTASSIUM-SPARING DIURETICS

Potassium-sparing diuretics (triamterene and amiloride) should be reserved for patients who experience hypokalemia while on a thiazide diuretic. With low-dose thiazide diuretics, less than 25% of patients develop hypokalemia, and most cases are not severe. Triamterene and amiloride usually do not provide significant additional BP lowering when added to a thiazide diuretic. Several fixed-dose products are available that include HCTZ with triamterene or amiloride. Empirically starting all patients with hypertension treated with a thiazide diuretic on triamterene or amiloride to avoid hypokalemia is not rational or necessary unless baseline serum potassium is in the low-normal range.

A thiazide diuretic is an optimal first-line option in primary prevention in patients like B.A., and she has no contraindications (Table 9-9). Although B.A. has dyslipidemia, thiazide diuretics are unlikely to have a clinically significant effect on cholesterol when used in low doses.[87,88] An appropriate starting dose of HCTZ is 12.5 or 25 mg daily. B.A. has no additional risks for orthostatic hypotension, so starting at the higher 25-mg daily dose is safe and will have a better chance of lowering her BP to goal than the lower 12.5-mg dose because most antihypertensive agents provide a 10-mm Hg reduction in SBP and 5-mm Hg reduction in DBP with a standard starting dose.[89]

Table 9-9

Side Effects and Contraindications of Antihypertensive Agents

	Side Effects			
	Innocuous but Sometimes Annoying	**Potentially Harmful**	**Usually Requires Cessation of Therapy, at Least Temporarily**	**Contraindications**
Thiazide diuretics	Increased urination (at onset of therapy), muscle cramps, hyperuricemia (without gout)	Hypokalemia,[a] hyponatremia, hyperglycemia, hypovolemia, pancreatitis, photosensitivity, hypercholesterolemia, hypertriglyceridemia, hyperuricemia with gout, orthostatic hypotension (more frequent in elderly)	Hypercalcemia, azotemia, skin rash (cross-reacts with only certain sulfonamide allergies), purpura, bone marrow depression, lithium toxicity in patients on lithium therapy, hyponatremia	Anuria, kidney failure
Loop diuretics	Increased urination, muscle cramps, hyperuricemia (less than with thiazides)	Hypokalemia,[a] hyperglycemia, hypovolemia, pancreatitis, hypercholesterolemia, hypertriglyceridemia,	Hyponatremia, hypocalcemia, azotemia, skin rash (cross-reacts with only certain sulfonamide	Anuria

		hearing loss with large IV doses, orthostatic hypotension (more pronounced in elderly)	allergies), photosensitivity, lithium toxicity in patients on lithium therapy	
ACEI	Dizziness, dry cough	Orthostatic hypotension (more pronounced in elderly treated with a diuretic), increased serum creatinine, increased potassium	Angioedema, severe hyperkalemia, increase in serum creatinine >35%	Bilateral renal artery stenosis, volume depletion, hyponatremia, pregnancy, history of angioedema
ARB	Dizziness	Orthostatic hypotension (more pronounced in elderly treated with a diuretic), increased serum creatinine, increased potassium	Severe hyperkalemia, increase in serum creatinine >35%	Bilateral renal artery stenosis, volume depletion, hyponatremia, pregnancy
CCB: dihydropyridines	Dizziness, headache, flushing	Peripheral edema, tachycardia	Significant peripheral edema	Left ventricular dysfunction (not with amlodipine or felodipine)
CCB: nondihydropyridines	Dizziness, headache, constipation	Bradycardia	Heart block, left ventricular dysfunction, interactions with certain drugs	Left ventricular dysfunction, second- or third-degree heart block, sick sinus syndrome
b-**Blocker**	Bradycardia, weakness, exercise intolerance	Masking the symptoms of hypoglycemia in diabetes, hyperglycemia, aggravation of peripheral arterial disease, erectile dysfunction, increased triglycerides, decreased HDL-C	Left ventricular dysfunction (not with carvedilol, metoprolol, bisoprolol), bronchospasm in patients with asthma or COPD (more pronounced with nonselective agents)	Severe asthma, second- or third-degree heart block, acute left ventricular dysfunction exacerbation, coronary artery disease for agents with intrinsic sympathomimetic activity
Aldosterone antagonist	Menstrual irregularities (spironolactone only) or gynecomastia (spironolactone only)	Increased potassium	Hyperkalemia, hyponatremia	Kidney failure. kidney impairment (for eplerenone: CrCl <50 mL/min, or type 2 diabetes with proteinuria, and creatinine >1.8 in women, >2.0 in men), hyperkalemia, hyponatremia

[a] Routine addition of potassium supplementation or empiric concurrent potassium-sparing diuretics should be discouraged unless hypokalemia is demonstrated, the patient is taking digoxin, or potassium is in the low-normal range.

ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin II receptor blocker; CCB, calcium-channel blocker; COPD, chronic obstructive pulmonary disease; CrCl, creatinine clearance; HDL-C, high-density lipoprotein cholesterol; IV, intravenous.

PATIENT EDUCATION

CASE 9-4, QUESTION 3: B.A. is prescribed HCTZ 25 mg daily. How should she be counseled regarding this therapy?

Several counseling points are summarized in Table 9-6. Some patients disregard lifestyle modifications when they start antihypertensive therapy, so B.A. must be encouraged to continue lifestyle modification to maximize her response to drug therapy. B.A. should be informed that diuretics lower both BP and risk of CV events and that taking her dose at about the same time each morning to minimize nocturia and provide consistent effects is recommended. B.A. should expect to experience increased urination when starting HCTZ, but should be informed that this diminishes with time. Inform B.A. that missed doses should be taken as soon as possible within the same day, but doubling doses the next day is not recommended. The potential for hypokalemia, which is easily identified and managed, and the need for routine monitoring of serum potassium should be reviewed. She should be counseled on the signs and symptoms of electrolyte abnormalities (e.g., leg cramps and muscle weakness) and encouraged to report these to her health care provider if they occur. Increasing dietary intake of potassium-rich foods to minimize electrolyte depletion is an option to minimize potassium loss. This should be encouraged only with thiazide and loop diuretics, but not with potassium-sparing agents.

Despite improvements with lifestyle modifications and reported adherence with HCTZ, B.A.'s goal BP of less than 140/90 mm Hg has not been met (her BP average is 141/83 mm Hg). No new signs of hypertension-associated complications are seen. She should be encouraged to continue with her current efforts, but other interventions are warranted.

CASE 9-4, QUESTION 4: After 4 weeks of HCTZ 25 mg daily, B.A. has no complaints and has not missed a dose. She is exercising and is following the DASH diet. Her BP values are 142/86 mm Hg (140/84 mm Hg when repeated). Her fasting laboratory values are as follows:

Serum potassium, 3.8 mEq/L
Uric acid, 7.3 mg/dL
Glucose, 99 mg/dL

All other values are unchanged. Last month, potassium was 4.0 mEq/L, uric acid was 6.8 mg/dL, and fasting glucose was 95 mg/dL. What is your assessment regarding the efficacy and toxicity of B.A.'s antihypertensive therapy?

POTASSIUM LOSS

Adverse reactions with low-dose thiazide diuretics (e.g., HCTZ 12.5–25 mg daily) are minimal compared with higher-dose therapy (HCTZ > 25 mg daily). Moreover, side effects and tolerability with low-dose thiazide diuretic therapy are similar to other first-line drug therapy options and not much higher than what is seen with placebo.[33,35,36] Regardless, signs and symptoms of electrolyte and metabolic changes, such as hypokalemia, hyponatremia, hyperglycemia, or hyperuricemia, should be evaluated in all patients treated with thiazide diuretics. B.A. has experienced small changes in serum potassium and uric acid, which are typical thiazide-induced abnormalities. B.A. should be questioned about muscle cramps or weakness, which can be caused by decreased potassium.

CASE 9-4, QUESTION 5: Is B.A.'s potassium decrease concerning? If so, how should this be managed?

Most total body potassium is intracellular (˜98%). Thiazide diuretics can cause potassium loss and can result in potassium serum concentrations in the low end of the normal range. However, with low-dose therapy, overt hypokalemia is not common. HCTZ in doses of 12.5, 25, and 50 mg daily can decrease serum potassium by an average of 0.21, 0.34, and 0.5 mEq/L, respectively.[33,87,88] This is usually considered mild, with serum potassium concentrations reaching a nadir within the first month of therapy and remaining stable thereafter. Restriction of dietary sodium in patients receiving diuretic therapy has been shown to reduce the loss of potassium and should be encouraged in B.A.[90]

Hypokalemia

CASE 9-4, QUESTION 6: When is potassium correction needed to manage diuretic-induced hypokalemia?

B.A.'s potassium is within the normal range. Potassium replacement is not indicated. Diuretic-associated hypokalemia should be treated when serum concentrations are below normal regardless of whether symptoms (e.g., muscle cramps) are present. Serum potassium should be measured at baseline and 2 to 4 weeks after initiating therapy or increasing the diuretic dose.

Potassium-rich foods (e.g., dried fruit, bananas, potatoes, and avocados) may help prevent small decreases in potassium, but they cannot be used as sole therapy to correct hypokalemia. For instance, one medium-size banana has only 11.5 mEq of potassium. The usual replacement dose of prescribed potassium chloride is 20 to 40 mEq/day but can range from 10 to more than 100 mEq/day. Potassium chloride, bicarbonate, gluconate, acetate, and citrate salts are available for potassium replacement therapy. Rather than supplement potassium, which does not effectively correct the underlying mechanisms responsible for hypokalemia, a more appropriate and effective strategy to manage diuretic-induced hypokalemia is to add a potassium-sparing diuretic. Hypomagnesemia often accompanies diuretic-induced hypokalemia and must be normalized before hypokalemia can be effectively reversed.

Other Metabolic Abnormalities

CASE 9-4, QUESTION 7: How should the increase in B.A.'s uric acid be managed?

Thiazide diuretics can increase serum uric acid concentrations in a dose-dependent fashion. Uric acid increases also occur with loop diuretics, but to a lesser extent. Increased proximal tubular renal reabsorption, decreased tubular secretion, or increased postsecretory reabsorption of uric acid contributes to diuretic-induced hyperuricemia. Thiazide-induced hyperuricemia is usually small (≤0.5 mg/dL) and is not clinically significant in patients without a history of gout.[89] For patients with a history of gout, diuretics are not contraindicated, but an increase in serum uric acid may require a decrease in dose or possibly discontinuation of the diuretic, especially for those not on preventive antihyperuricemic therapy (e.g., allopurinol and febuxostat). Acute gouty arthritis precipitated by diuretic therapy should be treated, and the diuretic should be discontinued, at least temporarily. Future use of the diuretic will depend on whether long-term antihyperuricemic therapy is to be added and the risk versus benefit for continuing the diuretic. B.A.'s serum uric acid concentration is elevated, but switching to a different agent or lowering the dose of HCTZ is unnecessary because she is not symptomatic of gout.

It should be noted that changes in parameters such as uric acid can be informative regarding dosing. When a given dose of a diuretic fails to lower BP, it is often unclear as to whether the failure is a result of mechanisms other than volume driving the hypertension or a result of the diuretic dose being insufficient to achieve the desired physiologic effect. For example, the absence of an increase in uric acid suggests that the administered dose was insufficient, and that a higher dose merits consideration. In B.A.'s case, the increase in uric acid confirms that the given dose was sufficient to have had a physiologic effect, so adding an antihypertensive agent from a different drug class would be preferable to increasing the diuretic dose if further BP lowering is necessary.

CASE 9-4, QUESTION 8: How much will HCTZ alter B.A.'s cholesterol values?

Small increases in LDL-C and triglycerides are potential side effects of diuretic therapy. Dietary fat restrictions help minimize, but do not necessarily prevent, these effects. Contrary to other biochemical disturbances, diuretic-induced changes in the lipid profile are not dose related, and overall changes are small. Many clinical trials lasting more than 1 year have shown that these alterations with diuretic therapy are not sustained with prolonged use.[87,88] Even if these changes are persistent, they are very small and are not clinically significant. The presence of dyslipidemia should never be a reason to avoid diuretic therapy.

CASE 9-4, QUESTION 9: What other potential electrolyte abnormalities should be evaluated in B.A. because of her thiazide diuretic therapy?

Hyponatremia is a serious, yet infrequent, adverse effect of diuretics. Changes in sodium concentrations are usually small, and the majority of patients are usually asymptomatic. Frail, elderly women appear more susceptible to experiencing severe hyponatremia (<120 mEq/L) from diuretics, which rarely occurs, but definitely requires discontinuation of therapy. Attention should be paid to the presence of other medications that can contribute to hyponatremia (e.g., selective serotonin reuptake inhibitors and psychotropic drugs), and patients should be counseled to avoid excessive free water intake.

Hypomagnesemia is an often overlooked metabolic complication of diuretic therapy. Both thiazide and loop diuretics increase urinary excretion of magnesium in a dose-dependent manner. Symptoms of significant hypomagnesemia include muscle weakness, muscle tremor or twitching, mental status changes, and cardiac arrhythmias. Presence of these symptoms would necessitate magnesium supplementation or use of a potassium-sparing agent as noted above if hypokalemia is also present.

Thiazide diuretics decrease urinary calcium excretion and can be used to prevent calcium-related kidney stones. The retention of calcium does not significantly increase serum calcium concentrations and does not place patients at risk for hypercalcemia. This effect, however, may be beneficial in women at risk for osteoporosis (e.g., postmenopausal) such as B.A. or in patients with osteoporosis. Conversely, loop diuretics increase renal clearance of calcium.

Reasons for Inadequate BP Control

CASE 9-4, QUESTION 10: What are common reasons for inadequate patient response to antihypertensive pharmacotherapy?

B.A. has been on her current dose of HCTZ for 4 weeks. The full antihypertensive effect of HCTZ has been achieved, but she still has uncontrolled hypertension. She has had a response, but it remains inadequate. Potential reasons for an inadequate response, or lack of attaining BP goal values, with an antihypertensive should be considered before modifying her drug therapy regimen (Table 9-10). A comprehensive medication history and medical evaluation is needed to rule out identifiable causes, in particular nonadherence to the prescribed regimen. Her BP reduction with HCTZ is typical. Her kidney function is good, and no evidence exists of edema, so volume overload is unlikely. There are no apparent secondary causes of elevated BP. It is reasonable to conclude that B.A. needs additional therapy to achieve her goal BP. It is very common that most patients require two or more agents to attain BP goal values.

Modifying Therapy

When patient cannot achieve optimal BP control with initial antihypertensive, JNC-8 recommends that the dose of the first drug may be increased (if patient has not yet achieved maximum dose of the agent), or low dose of a second agent may be added. Second agents of choice would be ACEI, ARB, CCB, or thiazide diuretics, whichever one the patient is not already taking.[2] B.A.'s present dose of HCTZ is appropriate and should not be increased to the maximal recommended dose of 50 mg daily (considered high-dose therapy) because it may increase risk of electrolyte and metabolic side effects. B.A.'s potassium dropped to 3.8 mEq/L with HCTZ, and further dosage increases may produce hypokalemia (<3.5 mEq/L) requiring correction. Her hyperuricemia may also be worsened. The slightly increased antihypertensive response expected from increasing to 50 mg/day is therefore not justified.[85] Discontinuing HCTZ and starting a different agent is an option, but it is not prudent to abandon the HCTZ; she tolerated the treatment and experienced a reasonable BP response, and the HCTZ will augment the efficacy of nearly any other agent that may be added and may benefit her osteoporosis.

Table 9-10

Reasons for Not Attaining Goal Blood Pressure Despite Antihypertensive Pharmacotherapy

Drug Related	Health Condition or Lifestyle Related	Other
Nonadherence	Volume overload	Improper blood pressure measurement
Inadequate antihypertensive dose	Excess sodium intake	Resistant hypertension
Inappropriate antihypertensive combination therapy	Volume retention from chronic kidney disease	White-coat hypertension
Inadequate diuretic therapy	Secondary disease causes (Table 9-2)	Pseudohypertension
Secondary drug-induced causes (Table 9-2)	Obesity	
Clinician's failure to intensify or augment therapy (i.e., clinical inertia)	Excessive alcohol intake	

TWO-DRUG REGIMENS

The role of two-drug regimens in the treatment of hypertension is very clear. Most patients require multiple agents for BP control.

Adding a second agent to B.A.'s regimen is needed to reduce BP to her goal. She is a primary prevention patient, so three potential add-on antihypertensive agents that are considered first-line include an ACEI, ARB, or CCB. Ideally, a combination of two drugs with different mechanisms of action should be selected to produce a complementary effect to lower BP.

Adding an ACEI or ARB to B.A.'s HCTZ will result in additive antihypertensive effects that are independent of reversing fluid retention. Diuretics reduce BP initially by decreasing fluid volume, but maintain their antihypertensive effects by lowering PVR. BP lowering, however, can stimulate renin release from the kidney and activate the RAAS. This compensatory mechanism is an in vivo attempt to neutralize BP changes and regulate fluid loss. An ACEI or an ARB blocks the RAAS, explaining why combinations of these agents with diuretics are additive. Data from the ACCOMPLISH trial support combination therapy for hypertension. In this randomized, double-blind trial, 11,506 patients with hypertension were randomly assigned to the combination of an ACEI with thiazide diuretic or an ACEI with CCB.[74] After a mean follow-up of 3 years, the risk of CV events was significantly lower with the ACEI with CCB combination. Switching B.A.'s HCTZ to an ACEI with CCB may be more effective in lowering CV events than adding an ACEI to her current HCTZ. This would be an acceptable modification. However, considering her response to HCTZ, simply adding an ACEI is also reasonable.

Fixed-Dose Combination Products

Several fixed-dose combination products including two or three drugs are available.

Although individual dose titration is not simple with fixed-dose combination products, their use can reduce the number of tablets or capsules taken by patients. This has been demonstrated to improve adherence compared with using two separate single-drug products.[91] Improved adherence may increase the likelihood of achieving goal BP values.

Most fixed-dose combinations include a thiazide diuretic, and many are available generically. Other fixed-dose combination products combine a CCB with either an ACEI or ARB. These combinations, similar to a thiazide with an ACE or ARB, are highly effective in lowering BP. An economic advantage may even exist to using a fixed-dose combination if it allows the patient to receive two drugs for one medication copayment. The Simplified Treatment Intervention To Control Hypertension study demonstrated that initiating therapy with a fixed-dose combination product according to a treatment algorithm was superior in attaining goal BP values when compared with usual management according to national guidelines.[92] These data further support using a fixed-dose combination product for initial therapy.

B.A. is a candidate for fixed-dose combination product. If the combination of an ACEI with HCTZ is selected for her, many options exist. All of the products with an ACEI also include HCTZ at the dose she is currently on. If the combination of an ACEI with a CCB is selected, fewer options exist, but there are products that contain an ACEI with a dihydropyridine CCB or a nondihydropyridine CCB. Cost should be considered because this is a concern for B.A. Multiple ACEI with thiazide diuretic combinations are available generically, but there is only one generic ACEI with CCB combination. Many ARBs are gradually becoming generic, so those may be potential option as well; therefore a combination of ARB plus thiazide diuretic may be an option too eventually.

Step-Down Therapy

CASE 9-5

QUESTION 1: T.J. is a 58-year-old man with a 10-year history of hypertension. He has been treated with lisinopril/HCTZ 20/25 mg daily and amlodipine 10 mg daily for more than 2 years, and his BP has been well controlled during this time. His BP at an office visit today is 128/74 and 130/72 mm Hg. He has no significant past medical history and has no hypertension-associated complications, but he is a smoker. T.J. also has dyslipidemia, which is well controlled with simvastatin 40 mg daily. He denies dizziness or difficulties with his medications. Should T.J.'s antihypertensive therapy be changed to reduce his medication doses or possibly discontinue some of his medications?

Some patients with hypertension can have their BP medications slowly withdrawn, resulting in normal BP values for weeks or months after discontinuation of their medications. This is called step-down therapy. However, it is not a feasible option for most patients with hypertension. Primary prevention patients with no additional major CV risk factors who have very well controlled BP for at least 1 year might be eligible for a trial of step-down therapy. This option should not be considered for patients with other major CV risk factors or hypertension-associated complications. Step-down therapy consists of attempting to gradually decrease the dosage, the number of antihypertensive drugs, or both without compromising BP control. Abrupt or large dosage reductions should be avoided because of the risk of rapid return of uncontrolled BP and even rebound surges in BP (as is seen with rapid withdrawal of a β-blocker or an α_2-agonist).

Step-down therapy is most often plausible for patients who have lost significant amounts of weight or have drastically changed their lifestyle. Any attempt at step-down therapy must be accompanied by scheduled follow-up evaluations because BP values can rise over the course of months to years after drug discontinuation, especially if lifestyle modifications are not maintained. With adherence to lifestyle modifications (weight loss and reduction in sodium and alcohol), nearly 70% of patients remained free of antihypertensives for up to 1 year after being withdrawn from thiazide-based therapy in the Hypertension Control Program.[93]

Step-down therapy in T.J. is not an option. Although he does not have hypertension-associated complications, he has multiple major CV risk factors for development of CV disease.

Angiotensin-Converting Enzyme Inhibitor

CASE 9-6

QUESTION 1: A.R. is a 49-year-old black woman with type 2 diabetes. She started lisinopril 10 mg daily 2 weeks ago when her BP values were around155/90 mm Hg. Since then, she has had weekly BP measurements, and her values have averaged 145/85 mm Hg despite strict adherence to her lifestyle modifications. Her BP today is 144/84 mm Hg (142/88 mm Hg when repeated), and her heart rate is 78 beats/minute. She is not a smoker, and her BMI is 29 kg/m^2. All her laboratory test results, including kidney function, are within normal limits, except that her spot urine albumin-to-creatinine ratio is 80 mg/g (2 weeks ago it was 90 mg/g). Is 2 weeks of lisinopril therapy long enough to assess her antihypertensive response?

Table 9-11

Angiotensin-Converting Enzyme Inhibitors in Hypertension

Drug	Usual Starting Dose (mg/day)[a]	Usual Dosage Range (mg/day)	Dosing Frequency
Benazepril	10	20–40	Daily to BID
Captopril	25	50–100	BID to TID
Enalapril	5	10–40	Daily to BID
Fosinopril	10	20–40	Daily
Lisinopril	10	20–40	Daily
Moexipril	7.5	7.5–30	Daily to BID
Perindopril	4	4–16	Daily
Quinapril	10	20–80	Daily to BID
Ramipril	2.5	2.5–20	Daily to BID
Trandolapril	1	2–4	Daily

[a] Starting dose may be decreased 50% if patient is volume depleted, has acute heart failure exacerbation, or is very elderly (≥75 year).

BID, 2 times daily; TID, 3 times daily.

Several ACEIs are available (Table 9-11). Most ACEIs are dosed once daily in hypertension (Table 9-11). In general, most ACEIs, if used in equivalent doses, are considered interchangeable.

The time to reach steady-state BP conditions is similar to what is seen with other antihypertensive agents. It may take several weeks before the full antihypertensive effects of ACEIs are seen. Therefore, evaluating BP response 2 to 4 weeks after starting or changing the dose of an ACEI is appropriate. A.R. has been taking lisinopril for 2 weeks, and her present BP should be used to determine whether she has attained goal. Both her BP range during the past few weeks and today's average BP are above her goal of less than 140/90 mm Hg.

CASE 9-6, QUESTION 2: Why should A.R. have serum potassium and serum creatinine monitored while on lisinopril therapy?

Serum potassium can increase with ACEI therapy as a result of aldosterone reduction. Potassium increases with ACEI monotherapy are small (typically 0.1 to 0.2 mEq/L) and usually do not cause hyperkalemia. This risk is increased when ACEIs are used in patients with significant CKD (GFR <60 mL/minute/1.73 m^2) or when they are used in combination with other drugs that can also raise potassium.

ACEI therapy can also cause a small increase in serum creatinine owing to decreased vasoconstriction of the efferent arteriole in the kidney. This results in a minor decrease in GFR that may be evidenced by a small increase in serum creatinine. A common mistake is to discontinue an ACEI in response to this rise in serum creatinine. Increases in serum creatinine of up to 30% from the baseline creatinine value are safe and anticipated. In these patients, the ACEI should be continued because a strong association exists between acute increases in serum creatinine of up to 30% that stabilize within the first 2 months of ACEI therapy and long-term preservation of renal function.[94] Patients with an increase in serum creatinine of greater than 30% should have their ACEI therapy temporarily discontinued, as this may indicate other medical problems. Some of these problems can be underlying renal disease (such as bilateral renal artery stenosis) or other situations that may be compromising renal blood flow (e.g., volume depletion, concomitant nonsteroidal antiinflammatory drug therapy, and heart failure). Serum potassium and serum creatinine, in addition to BP, should be monitored in A.R. within 2 to 4 weeks after starting ACEI therapy or increasing the dose.

CASE 9-6, QUESTION 3: A.R.'s lisinopril dose is increased to 20 mg daily. Will this doubling of her dose place her at risk for significant hypotension?

The very elderly patients with volume depletion or patients with heart failure exacerbation may experience a significant first-dose response to an ACEI. This can manifest as orthostatic hypotension, dizziness, or syncope. The increased pretreatment activity of the RAAS, coupled with blockade of this system, explains this effect. In these patients, ACEI therapy should be initiated at half the normal dose (Table 9-11), followed by slow titration to standard doses.

Concurrent diuretic therapy may predispose some patients to first-dose hypotension. When ACEIs were first approved, dosing guidelines recommended starting at half the standard dose of the ACEI, decreasing the dose of the diuretic, or stopping the diuretic before initiating the ACEI. This was owing to fear that BP would sharply and acutely drop. These dosing recommendations are not necessary unless the patient is hemodynamically unstable (volume depleted, hyponatremic, or poorly compensated heart failure) or very elderly. A.R. does not have any of these characteristics and can safely increase her dose of lisinopril.

CASE 9-6, QUESTION 4: Is an ACEI an effective therapy in a black patient such as A.R.?

ACEI monotherapy is generally more effective at lowering BP in white patients than in black or elderly patients. In fact, JNC-8 guideline does not recommend the use of ACEI or ARB as first-choice antihypertensive in black patients for primary prevention, including those with diabetes (unless they have CKD).[2] Elderly and black patients are more likely to have low renin hypertension, which may partially explain some of the differences in response. Nevertheless, many of these patients still respond to ACEIs as monotherapy just to a less extent. Combination therapy, especially with a thiazide diuretic, usually mitigates this race- and age-related difference in BP response.

When an antihypertensive agent is being selected as initial monotherapy in a black patient, an ACEI should generally not be chosen unless the patient has CKD. A thiazide diuretic or CCB is otherwise preferred. In this case, considering switching to a different agent (thiazide and CCB) may be a good alternative to improve A.R.'s BP control. Of note, black patients have a twofold to fourfold increased risk of angioedema and cough with ACEIs compared with white patients.[95] This does not preclude ACEI use in black patients unless there is a prior history of angioedema.

CASE 9-6, QUESTION 5: A.R. has microalbuminuria, and lisinopril may help preserve kidney function. However, is there a risk that lisinopril can cause acute renal dysfunction?

The ACEIs are effective in patients with hypertension-associated renal disease. They are contraindicated, however, in several situations, including bilateral renal artery stenosis, pregnancy, and volume depletion (Table 9-9). In the case of bilateral renal artery stenosis or volume depletion, high angiotensin concentrations maintain renal blood flow, and acute renal dysfunction can occur when an ACEI is started. Because it is often not known whether a patient has bilateral renal artery stenosis, problems with ACEI can be minimized by starting with recommended doses and careful monitoring of serum creatinine within 2 to 4 weeks of starting therapy. Modest elevations in serum creatinine that are less than 30% (for baseline creatinine values <3.0 mg/dL) do not warrant adjustment in therapy.[94] If greater increases occur, ACEI therapy should be stopped, and further medical evaluation should occur. Patients with elevated serum creatinine at baseline (up to

---

3.0 mg/dL) may particularly benefit from the vasodilatory effects of ACEIs in the kidney, but require careful drug initiation and close monitoring. A.R.'s serum creatinine was normal after 4 weeks of lisinopril therapy. She is not experiencing any kidney-related adverse effects from lisinopril.

CASE 9-6, QUESTION 6: What are the risks of using ACEIs in women of childbearing age?

Because ACEIs are teratogenic in the second and third trimester,[96] their use in pregnancy is contraindicated. Moreover, their use in women of childbearing potential is discouraged. If used in this population, patient education should be explicitly clear regarding risks to the fetus, which include potentially fatal hypotension, anuria, renal failure, and developmental deformities. A highly effective form of contraception should be strongly recommended.

Angiotensin Receptor Blockers

CASE 9-6, QUESTION 7: A.R.'s lisinopril is increased to 20 mg daily, then to 40 mg daily during a period of 8 weeks. Her current BP is 136/78 mm Hg (134/76 mm Hg when repeated) at an office visit today. Her serum potassium and creatinine are unchanged from previous values. However, she reports a persistent dry cough for the past few months. She has no additional signs suggesting upper respiratory infection or left ventricular dysfunction. How should A.R.'s therapy be modified?

A well-known side effect of ACEIs is a nonproductive, dry cough, which can occur in up to 15% of patients, with some estimates of cough prevalence being higher.[97] Patients may describe this as a tickling sensation in the back of the throat that commonly occurs late in the evening. This is distinctly different from the cough associated with left ventricular dysfunction, which might be associated with crackles and rales (on auscultation) indicating possible pulmonary edema. ACEI-related cough resolves with discontinuation. Many agents have been used to treat an ACEI cough with poor results. The best treatment option for a patient with an intolerable ACEI cough is to switch agents.

CASE 9-6, QUESTION 8: How is an ARB different from an ACEI?

For A.R., switching to an ARB would likely eliminate the cough.[98] Although her first-choice antihypertensive should be CCB or thiazide diuretics, A.R. will also require the addition of a second agent, either a CCB or thiazide diuretic, because she has not achieved her goal BP of less than 130/80 mm Hg. ARBs are first line. There are eight ARBs (Table 9-12), and many are available as two-drug fixed-dose combination products (Online Table 9-1), as well as two different three-drug fixed-dose combination products (Online Table 9-2).

PHARMACOLOGIC DIFFERENCES BETWEEN AN ANGIOTENSIN-CONVERTING ENZYME INHIBITOR AND AN ANGIOTENSIN RECEPTOR BLOCKER

Unlike ACEIs, ARBs specifically bind to angiotensin II receptors in vascular smooth muscle, adrenal glands, and other tissues. Access of angiotensin II to its receptors is blocked, and angiotensin I-mediated vasoconstriction and aldosterone release is prevented, resulting in BP reduction. ARBs do not affect bradykinin; therefore dry cough does not occur.

Considerable investigation has focused on describing the pharmacologic differences between the angiotensin II type 1 and type 2 receptors. Stimulation of the type 1 receptor causes vasoconstriction, salt and water retention, and vascular remodeling. Other deleterious effects from type 1 receptor stimulation include myocyte and smooth muscle hypertrophy, fibroblast hyperplasia, cytotoxic effects in the myocardium, altered gene expression, and possible increased concentrations of plasminogen activator inhibitor. Stimulation of the type 2 receptor results in antiproliferative actions, cell differentiation, and tissue repair.

Table 9-12

Angiotensin Receptor Blockers in Hypertension

Drug	Starting Dose (mg/day)[a]	Usual Dosage Range (mg/day)	Dosing Frequency
Azilsartan medoxomil	80	80	Daily
Candesartan cilexetil	16	8–32	Daily to BID
Eprosartan mesylate	600	600–800	Daily to BID
Irbesartan	150	75–300	Daily
Losartan potassium	50	25–100	Daily to BID
Olmesartan medoxomil	20	20–40	Daily
Telmisartan	40	20–80	Daily
Valsartan	80–160	80–320	Daily

[a] Starting dose may be decreased 50% if patient is volume depleted, very elderly, or taking a diuretic.
BID, 2 times daily.

CASE 9-6, QUESTION 9: Under what circumstances would an ARB be a more appropriate initial antihypertensive agent than an ACEI?

Theoretically, an ideal antihypertensive agent would block only type 1 and not type 2 receptors as is the case with ARBs. Therefore, it is possible that an ARB would be superior to an ACEI in reducing hypertension-associated complications because ACEIs ultimately decrease stimulation of both type 1 and type 2 receptors by decreasing production of angiotensin II. This argument is purely speculative and is not supported by clinical trial data. ONgoing Telmisartan Alone and in Combination With Ramipril Global Endpoint Trial (ONTARGET) was a prospective, double-blind, randomized controlled trial that directly compared ARB-based therapy, ACEI-based therapy, and the combination of an ACEI with ARB.[99] After a median of 56 months, the incidence of CV events was no different among all three treatment groups. Therefore, ARB therapy is as effective as, but no more superior than, ACEI therapy in the overall management of hypertension.

CASE 9-6, QUESTION 10: If A.R. experienced angioedema from lisinopril, would treatment with an ARB be appropriate?

A history of ACEI-induced angioedema does not preclude the use of ARB therapy.

The cross-reactivity between angioedema with an ACEI and ARB is not exactly known. The Candesartan in Heart Failure: Assessment of Reduction in Mortality and Morbidity Alternative study prospectively included patients with a history of ACEI intolerance who were randomly assigned, in a double-blind manner, to placebo or candesartan. Of the 2,028 patients enrolled, 39 had a history of ACEI angioedema, and only 1 of these patients experienced repeat angioedema that required discontinuation of the ARB.[99] In the Telmisartan Randomised Assessment Study in ACE Intolerant Subjects with Cardiovascular Disease trial, 5,926 patients with a history of ACEI intolerance were randomly assigned in this double-blind trial to an ARB or placebo for a median duration of 56 months.[100] A total of 75 patients had a history of ACEI angioedema, and none of those patients who were randomly assigned to the ARB treatment arm experienced repeat angioedema. Therefore, cross-reactivity in angioedema between ACEIs and ARBs appears possible, but unlikely and very small. ARBs are an alternative for patients who experience ACEI angioedema but should be reserved for patients with a compelling indication for an ACEI. Of note, the ACC/AHA guidelines recommend an ARB in patients who have experienced angioedema from an ACEI.[79]

Calcium-Channel Blockers

CCBs effectively lower BP. Elderly and black patients generally have greater BP reduction with a CCB than with other agents (β-blockers, ACEIs, and ARBs). The addition of a diuretic to a CCB provides additive antihypertensive effects. CCBs do not alter serum lipids, glucose, uric acid, or electrolytes.

All CCBs inhibit the movement of extracellular calcium, but there are two primary subtypes: dihydropyridines and nondihydropyridines (i.e., diltiazem and verapamil). Each has distinctly different pharmacologic effects.

DIHYDROPYRIDINE CALCIUM-CHANNEL BLOCKERS

Dihydropyridines are potent vasodilators of peripheral and coronary arteries. They do not block AV nodal conduction and do not treat arrhythmias. Moreover, the potent vasodilation associated with most dihydropyridines can induce a reflex tachycardia. With the exception of amlodipine and felodipine, dihydropyridines decrease cardiac contractility and should be avoided in patients with left ventricular dysfunction. Side effects of dihydropyridines are related to their potent vasodilatory effects (e.g., tachycardia, headache, and peripheral edema).

Peripheral edema with CCB therapy, especially a dihydropyridine CCB, is a dose-dependent side effect. It is a direct result of the potent peripheral arterial vasodilation. When there is not equal vasodilation in the venous vasculature, a risk exists for leaking through the capillaries in the legs and, thus, an increased risk of peripheral edema. The best way to manage this side effect is to reduce the dose of the dihydropyridine or to add an agent that blocks the RAAS to decrease the effects of angiotensin II, which will result in a more balanced pressure gradient across her peripheral vasculature by providing vasodilation of both the arteries and veins. Adding either an ACEI or ARB can be used to accomplish this with the added benefit of further lowering BP. Clinicians should note that using diuretics for the primary purpose of treating peripheral edema that is secondary to CCB use is not recommended and is not effective.

NONDIHYDROPYRIDINE CALCIUM-CHANNEL BLOCKERS

The two nondihydropyridine CCBs, diltiazem and verapamil, are similar to each other. Relative to dihydropyridines, they are only moderately potent vasodilators, but they directly decrease AV nodal conduction and have greater decreases in cardiac contractility. The blockade of AV nodal conduction can slow heart rate and is the basis for their use in controlling supraventricular tachycardias associated with certain arrhythmias (e.g., atrial fibrillation). Most patients only have a modest decrease in heart rate. However, heart block (first, second, or third degree) is a potential adverse effect, especially with large doses. Both diltiazem and verapamil should be avoided in patients with an underlying second- or third-degree heart block. Under these circumstances, a dihydropyridine can be used if a CCB is needed. Verapamil and diltiazem should be avoided in patients with left ventricular dysfunction because they can significantly reduce cardiac contractility. When patients with left ventricular dysfunction require a CCB to treat another condition (i.e., angina or hypertension), amlodipine or felodipine may be used. They are the only CCBs that have been safely used in clinical trials of patients with left ventricular dysfunction. Unlike many other antihypertensive agents, they do not, however, protect against left ventricular dysfunction-related mortality. Diltiazem may have a lower incidence of constipation than verapamil. Verapamil is also an effective agent in migraine prophylaxis and can be used if patients also have migraine. Patients with Raynaud phenomenon can obtain symptomatic relief from the peripheral vasodilation associated with a dihydropyridine CCB. Lastly, CCBs are effective in treating cyclosporine-induced hypertension, but should be used cautiously because verapamil and diltiazem increase cyclosporine concentration.

OTHER CONSIDERATIONS

Formulations

Several CCBs are available for the treatment of hypertension. They are listed in Table 9-13. Immediate-release formulations should be avoided (see Chapter 16, Hypertensive Crises).

Sustained-Release Formulations

CASE 9-7

QUESTION 1: C.F. is a 60-year-old man with hypertension, asthma, and type 2 diabetes. His hypertension is treated with HCTZ 25 mg daily and ramipril 20 mg daily for many years. Today his BP is 148/74 mm Hg (144/72 mm Hg when repeated), and his heart rate is 90 beats/minute. C.F.'s physician would like to add a CCB to his regimen to improve BP control. What are the differences between controlled-onset, extended-release verapamil and sustained-release verapamil? Are they interchangeable?

All CCBs have short half-lives, except amlodipine. Immediate-release forms require multiple daily doses to provide 24-hour effects. Sustained-released formulations are preferred when a CCB is used to treat hypertension. Various sustained-release delivery devices are available. Serum drug concentrations differ among sustained-release CCBs, but overall BP lowering is usually similar. Nonetheless, most of these products that include the same drug are not rated by the US Food and Drug Administration as equivalent and identical. Insurance formularies often encourage therapeutic substitution between these agents. Therapeutic interchange between modified-release drug delivery formulations that allow for once- or twice-daily dosing (e.g., sustained-release, extended-release, and chronotherapeutic products), however, are not equivalent using a milligram-per-milligram conversion. Therapeutic substitution among these products may result in variable BP-lowering effects if not adjusted appropriately. BP and heart rate monitoring should occur within 2 weeks of interchanging sustained-release CCBs.

CASE 9-7, QUESTION 2: Is there any clinical evidence on the use of CCB in diabetic outcomes?

CALCIUM-CHANNEL BLOCKER AND DIABETES

CCBs have been shown to reduce risk of CV events in patients with diabetes,[98] although the evidence is not as convincing as that seen with an ACEI. The results of the Fosinopril versus Amlodipine Cardiovascular Events Randomized Trial and Appropriate Blood Pressure Control in Diabetes trial suggest that ACEIs have more CV protection than CCBs.[56,57]

Table 9-13

Calcium-Channel Blockers in Hypertension[a]

Drug	Usual Dosage Range (mg/day)	Dosing Frequency
Nondihydropyridines[b]		
Diltiazem, sustained release	120–480	Daily
Diltiazem, extended release[c]	120–540	Daily
Verapamil, sustained release	180–480	Daily to BID

Verapamil, controlled-onset extended release[c]	180–480	QHS
Verapamil, chronotherapeutic oral drug absorption system[c]	100–400	QHS
Dihydropyridines		
Amlodipine	2.5–10	Daily
Felodipine, extended-release tablet	2.5–10	Daily
Isradipine, controlled-release tablet	5–20	Daily
Nicardipine, sustained-release capsule	60–120	BID
Nifedipine, sustained-release tablet[d]	30–90	Daily
Nisoldipine, extended-release tablet	17–34	Daily

[a] Immediate-release (IR) diltiazem, nifedipine, and verapamil should be avoided in hypertension.

[b] Many different long-acting products exist. Because their individual release characteristics vary, they are not exactly interchangeable using a milligram-per-milligram conversion.

[c] Chronotherapeutic agents are dosed primarily at bedtime and have a delayed drug release for a period of hours, followed by slow delivery of drug that starts just before morning, with no delivery during the early evening; because they use different delivery systems, they are not interchangeable products.

[d] Only sustained-release nifedipine is approved for hypertension. Immediate-release nifedipine should be avoided for the management of hypertension.

BID, 2 times daily; QHS, every night.

Nondihydropyridine CCBs (particularly diltiazem) may slow the progression of CKD, although evidence is not as extensive or definitive as it is with an ACEI or ARB. The proposed mechanism is dilation of both the afferent and efferent arterioles, which would decrease intraglomerular pressure. Dihydropyridines have unclear effects on progression of kidney disease. The prevailing opinion is that the renal protective effects of an ACEI and ARB are superior to that of a CCB.

Resistant Hypertension

CASE 9-8

QUESTION 1: R.R. is a 52-year-old man with hypertension for 10 years. He has not yet experienced any hypertension-associated complications or target-organ damage. He does not have a history of diabetes and does not smoke. He has been treated with HCTZ 25 mg daily, amlodipine 10 mg daily, valsartan 320 mg daily, and carvedilol 12.5 mg twice daily for 1 year. He reports rarely missing a dose of his medications, measures his BP at home every day, and follows recommended lifestyle modifications as diligently as possible. He has tried other medications that resulted in intolerances (doxazosin, dizziness; clonidine, dry mouth). His BP has never been less than 140/90 mm Hg, which is his goal. His BP today is 150/90 mm Hg (152/92 mm Hg when repeated), his heart rate is 60 beats/minute, serum potassium is 4.2 mEq/L, and serum creatinine is 1.0 mg/dL. He is 183 cm tall and weighs 85 kg. Does R.R. have resistant hypertension? What are his treatment options?

R.R. has resistant hypertension. JNC-8 guidelines recommends that, if goal BP is not reached within a month of treatment of initial drug treatment, increase the dose of the initial drug or add a second drug from one of the first-choice classes of antihypertensives (thiazide diuretic, CCB, ACEI, or ARB). If goal BP cannot be reached with maximal tolerable doses of two drugs, add and titrate a third drug from the preferred provided. Do not use an ACEI and an ARB together in the same patient.[2] If goal BP cannot be reached using only the drugs in the preferred list, because of a contraindication or the need to use more than three drugs to reach goal BP, antihypertensive drugs from other classes can be used. Referral to a hypertension specialist may be indicated for patients in whom goal BP cannot be attained using the above strategy or for the management of complicated patients for whom additional clinical consultation is needed to rule out secondary causes of hypertension. R.R.'s treatment options are limited. Amlodipine and valsartan are both at the maximal doses. Carvedilol could be increased to 25 mg twice daily, but this should not be done because his heart rate is 60 beats/minute and increasing this dose would place him at risk for bradycardia. It is possible to increase HCTZ to 50 mg daily because this higher dose provides larger BP reductions than 12.5 or 25 mg daily based on 24-hour ABPM.[85] The limitation of this approach is an increased risk of electrolyte abnormalities and metabolic side effects.

CASE 9-8, QUESTION 2: How safe is it to add lisinopril 5 mg daily or spironolactone 25 mg daily in R.R.?

For resistant hypertension, three global treatment philosophies should be considered: (a) assuring appropriate diuretic therapy, (b) appropriate use of effective drug combination, and (c) use of alternative antihypertensive agents as appropriate.[13] Adding an ACEI to an already maximum dose of valsartan would not be recommended. The combination of an ACEI and ARB overall is not very beneficial. This combination should not be used specifically for the purpose of BP lowering, especially in primary prevention patients. When this combination was evaluated in the ONTARGET, the ACEI with ARB combination treatment arm provided only minimal additional reduction in BP compared with either agent alone and most importantly did not additionally lower risk of CV events. Moreover, there was a higher risk of

---

adverse events (e.g., kidney dysfunction and hypotension) with the combination arm.

The combination of an ACEI with ARB has been used in patients with left ventricular dysfunction based on promising data of a reduced risk of heart failure hospitalizations.[101,102] However, the overall clinical benefits of an ACEI with an ARB versus an ACEI without an ARB are very small; addition of an aldosterone antagonist is the preferred next step in patients with left ventricular dysfunction who are already treated with the standard regimen of a diuretic, ACEI, and a β-blocker.[79] One potential niche for the use of an ACEI with an ARB is in the setting of CKD with significant proteinuria (300 mg albumin/day or 500 mg protein/day or per gram of urinary creatinine), in which the combination of an ACEI with an ARB seems to reduce progression of proteinuria better than either drug alone.[73]

Many patients with resistant hypertension have a significant component of volume expansion. Detecting this may not be easily observed using routine clinical examinations. However, identifying occult volume expansion using serial hemodynamic measurements from noninvasive bioimpedance testing, followed by enhancing diuretic therapy, has been shown to reduce BP better than treatment selected by an experienced hypertension specialist.[103] Options to assure appropriate diuretic therapy include switching diuretic agents, switching diuretic classes, increasing the dose, or adding a different class of diuretic. Instead of increasing HCTZ to 50 mg daily, switching HCTZ to the more long-acting chlorthalidone is another possible option to enhance BP lowering. This is an option in R.R. Another option is switching HCTZ to a loop diuretic (e.g., furosemide or torsemide). This should be considered for patients with stage 4 or 5 CKD (GFR <30 mL/minute/1.73 m^2) or for those who need diuresis because of edema. This is not a reasonable treatment option for R.R. because he does not have CKD. Another option is to add an aldosterone antagonist, which is considered an alternative antihypertensive agent. Patients with resistant hypertension often require the use of an agent(s) (Table 9-14) that is not widely used as either a first- or a second-line therapy. These therapies should not be used as monotherapy or a cornerstone of a multidrug regimen because there is less evidence to support their role in reducing CV events. It should be acknowledged, however, that some of these agents (e.g., reserpine and hydralazine) served as add-on agents to diuretics and β-blockers in early placebo-controlled, stepped-care approach trials in hypertension. R.R. has already failed to fully respond to, or tolerate, several drug classes that typically are associated with reductions in hypertension-associated complications. To attain his BP goal of less than 140/90 mm Hg, an alternative agent, other than clonidine, should be selected because he did not tolerate it in the past.

Table 9-14

Alternative Antihypertensive Agents

Drugs/Mechanism of Action	Usual Dosage Range (mg/day)	Dosing Frequency
Aldosterone Antagonists (see Table 14-9)		
α_1-Blockers		
Doxazosin	1–8	Daily
Prazosin	2–20	BID to TID
Terazosin	1–20	Daily to BID
Direct Renin Inhibitor		
Aliskiren	150–300	Daily

α2-Agonists (Central)		
Clonidine	0.1–0.8	BID
Clonidine	0.17–0.52	Daily
Clonidine transdermal	0.1–0.3	Once weekly
Methyldopa	250–1,000	BID
Arterial Vasodilators		
Hydralazine	25–100	BID to TID
Minoxidil	2.5–80	Daily to BID
Adrenergic Neuron Blockers		
Reserpine	0.05–0.25	Daily

BID, 2 times daily; TID, 3 times daily.

ALTERNATIVE ANTIHYPERTENSIVE AGENTS

Aldosterone Antagonists

Spironolactone and eplerenone are aldosterone antagonists that are especially useful as an add-on therapy in patients with resistant hypertension and would be a reasonable addition to R.R.'s regimen.[8,104] Many patients with resistant hypertension have increased activation of the RAAS, which can result in increased aldosterone. Moreover, up to 20% of patients with resistant hypertension have primary aldosteronism.[8] These characteristics of patients with resistant hypertension make the addition of an aldosterone antagonist very effective in lowering BP in resistant hypertension.

R.R.'s potassium is in the normal range, but could increase after adding spironolactone. Therefore, it should be monitored 2 to 4 weeks after therapy is started to assure R.R. does not experience hyperkalemia. Eplerenone is more specific than spironolactone in aldosterone blockade, although some data suggest that spironolactone is more effective in primary aldosteronism.[105] Compared with spironolactone, gynecomastia is less frequent with eplerenone. The incidence of hyperkalemia may be greater with eplerenone, however. When used for hypertension, eplerenone is contraindicated in populations at high risk for hyperkalemia including patients with an estimated creatinine clearance of less than 50 mL/minute or elevated serum creatinine (>1.8 mg/dL in women and >2.0 mg/dL in men).

CASE 9-8, QUESTION 3: How beneficial would more intensive lifestyle modifications be in R.R.?

In addition to nonadherence with drug therapy, lifestyle factors (obesity, sodium ingestion, and heavy alcohol intake) are a significant contributor to resistant hypertension.[8] Lifestyle modifications should continually be reinforced in patients, especially those with resistant hypertension. As previously discussed, these modifications should include dietary changes and physical activity. R.R should be instructed to restrict his daily sodium to less than 1.5 g because this has been shown to decrease SBP by more than 20 mm Hg in resistant hypertension.[23]

α-Blockers

CASE 9-9

QUESTION 1: J.L. is a 64-year-old man with hypertension. His BP is 158/84 mm Hg (156/86 mm Hg when repeated). His current antihypertensive regimen is HCTZ 25 mg daily, irbesartan 300 mg daily, and nifedipine extended-release 60 mg daily. J.L. is not completely adherent with lifestyle modifications, but insists he is doing the best he can. He has been experiencing frequent nocturia, difficulty in starting urination, and a decrease in his urinary flow for the past several months and is diagnosed with benign prostatic hyperplasia (BPH). J.L.'s physician is considering changing one of his antihypertensive agents to an α-blocker. How do α-blockers compare with other agents in reducing CV events?

α-Blockers are not first-line agents in the management of hypertension. The ALLHAT trial originally included an α-blocker (doxazosin) treatment arm.[48] Interim results after a mean follow-up of 3.3 years revealed that doxazosin had a statistically higher risk of combined CV disease and heart failure when compared with chlorthalidone.[106] Therefore, the ALLHAT data show that chlorthalidone was more effective in lowering some hypertension-associated complications than was doxazosin. This study did not include a placebo group; therefore, to conclude that doxazosin is harmful is inaccurate. For J.L., discontinuing HCTZ, irbesartan, or nifedipine to start an α-blocker is not prudent. It may be appropriate, however, to add an α-blocker to his regimen; an α-blocker will also have a benefit on his BPH (Table 9-7).

CASE 9-9, QUESTION 2: How can an α-blocker improve J.L.'s BPH?

The smooth muscle surrounding the prostate is innervated by α_1-receptors. By blocking these receptors, an α-blocker can improve the symptoms of BPH by reducing urethral tone and alleviating bladder outlet obstruction. Terazosin and doxazosin are both approved for the treatment of BPH. Prazosin should not be used because of the need for frequent dosing. Improvements in BPH symptoms with α-blockers are dose related. A high dose is often needed, and this increases the risk of side effects, such as orthostatic hypotension. In J.L., an α-blocker will lower his BP and improve his urinary symptoms.

CASE 9-9, QUESTION 3: J.L. prefers to try doxazosin rather than undergo surgery to relieve his symptoms of BPH. How should this agent be started?

For J.L., it would be best to add a low dose of doxazosin to his present regimen. Based on his BP response and tolerance, the dose can be titrated up. One of his other antihypertensive agents can be decreased if he becomes hypotensive. The initial dose of doxazosin should not exceed 1 mg daily and it should be given at bedtime. This can minimize orthostatic hypotension, which is the most frequent side effect of α-blockers. This complication is most pronounced with the first dose, but can persist in some patients. Moreover, if an α-blocker is selected as add-on therapy in patients like J.L. with resistant hypertension, nighttime administration of an α-blocker has been shown to be effective in further lowering BP.[107]

CASE 9-9, QUESTION 4: How should J.L. be counseled regarding side effects of doxazosin?

α-Blockers are well tolerated if dosed appropriately. J.L. could experience side effects, such as drowsiness, headache, weakness, palpitations from reflex tachycardia, and nausea, but these do not occur in all patients. Patients starting an α-blocker should be instructed to take the initial dose at bedtime and to anticipate the first-dose effect of orthostatic hypotension. Specifically, patients should be counseled to rise more slowly from a seated or supine position.

Miscellaneous Agents

ALISKIREN

CASE 9-10

QUESTION 1: R.P. is a 68-year-old man with hypertension and a history of ischemic stroke (1 year ago). Two months ago, his BP value was 164/94 mm Hg (162/98 mm Hg when repeated), with a heart rate of 62 beats/minute while on sustained-release diltiazem 240 mg daily. He was started on benazepril/HCTZ 10/12.5 mg daily 2 months ago. His BP today is 142/82 mm Hg (144/82 mm Hg when repeated). All his laboratory values are normal except his serum creatinine, which is 1.9 mg/dL. J.L. has implemented lifestyle modification to the best of his ability. His physician is wondering if aliskiren be added to his drug regiment considering he is also on ACEI.

DIRECT RENIN INHIBITORS

Aliskiren is a direct renin inhibitor. It inhibits the first step of the RAAS, which results in reduced PRA and BP lowering.

CASE 9-10, QUESTION 2: How is aliskiren different from an ACEI or ARB?

This is different from the decreased production of angiotensin II with ACEIs and the blocked angiotensin II receptor effects with ARBs; however, BP-lowering effects are similar to those with ACEIs and ARBs. Aliskiren has a 24-hour half-life and, similar to most ACEIs and ARBs, is dosed once daily.

Some similarities and some differences exist among the side effects associated with aliskiren when compared with ACEIs and ARBs. Aliskiren should not be used in pregnancy because of the known teratogenic effects from blocking the RAAS system. Increases in serum creatinine and serum potassium have been associated with aliskiren. These are similar to ACEI and ARB therapy and are mediated by the inhibition of angiotensin II vasoconstrictive effects on the efferent arterioles of the kidney and blocking of aldosterone. Monitoring of serum creatinine and serum potassium should be done in patients treated with aliskiren, particularly in those treated with the combination of aliskiren and an ACEI, ARB, potassium-sparing diuretic, or aldosterone antagonist. Angioedema has also been reported in patients treated with aliskiren.

CASE 9-10, QUESTION 3: What is the role of aliskiren in treating R.P.'s hypertension?

The exact role of aliskiren in treatment of hypertension is unclear. It is approved as monotherapy or in combination therapy. The BP reductions with aliskiren as monotherapy are similar to those seen with an ACEI, ARB, or CCB (specifically amlodipine). Aliskiren provides additive BP lowering when used in combination with HCTZ, ACEI, ARB, and CCB. Its efficacy in combination with maximal doses of ACEI is unknown, however. Aliskiren is an alternative antihypertensive agent at this time because of unknown long-term effects on CV events.

MIXED αβ-BLOCKERS AND NEBIVOLOL

Labetalol and carvedilol (Table 9-15) are nonselective β-blockers that also have α_1-receptor blocking activity. Their antihypertensive effects are only somewhat similar to a combination of a nonselective β-blocker with an α_1-antagonist.

These agents produce vasodilation because of the α-blocker effects. The only other β-blocker that provides vasodilation is nebivolol. However, nebivolol produces vasodilation without blockade of α-receptors. The same precautions and contraindications relevant to nonselective β-blockers apply to both carvedilol and labetalol because they block both β_1- and β_2-receptors (Table 9-9).

Carvedilol is approved for both hypertension and left ventricular dysfunction. Carvedilol has been shown to reduce morbidity and mortality in a wide range of patients with left ventricular dysfunction.[108,109] Labetalol and carvedilol have no clear advantage over other β-blockers in most patients with hypertension, with the exception that they offer a dual mechanism of action within a single drug formulation. In patients with type 2 diabetes, carvedilol has been shown to have no significant effect on glucose in comparison with metoprolol, which may slightly increase glucose.[110]

Table 9-15

Common β-Blockers in Hypertension

Drug	Usual Dosage Range (mg/day)	Dosing Frequency	Half-Life (hours)	β1-Selectivity	Lipid Solubility
Atenolol	25–100	Daily to BID	6–7	++	Low
Bisoprolol	5–20	Daily	9–12	+++	High
Carvedilol	12.5–50	BID	6–10	0	High

Carvedilol	10–80	Daily	6–10	0	High
Labetalol	200–800	BID	6–8	0	Moderate
Metoprolol tartrate	100–400	BID	3–7	+	Moderate to high
Metoprolol succinate	25–400	Daily	3–7	+	Moderate to high
Nebivolol	5–10	Daily	12–19	+++	High
Propranolol	40–180	Daily (LA and XL) or BID	3–5	0	High

BID, 2 times daily.

CENTRAL α_2-AGONISTS

The antihypertensive effects of α_2-agonists (Table 9-14) are attributed to their central α_2-agonist activity. Stimulation of α_2-receptors in the CNS inhibits sympathetic outflow (via negative feedback) to the heart, kidneys, and peripheral vasculature, resulting in peripheral vasodilation. Although the α_2-agonists effectively lower BP, they have many potential side effects and have not been evaluated in trials focused on CV events.

Clonidine

CASE 9-11

QUESTION 1: T.M. is a 43-year-old man. He is a truck driver with a 5-year history of hypertension. He does not have hypertension-associated complications. Secondary causes have been ruled out. His regimen is losartan/HCTZ 100/25 mg daily and sustained-release diltiazem 240 mg daily. Other antihypertensive drugs have failed because of various side effects (captopril and lisinopril, dry cough; atenolol and carvedilol, fatigue; nifedipine and amlodipine, edema; terazosin, orthostasis). T.M. has been adherent with his present medications and lifestyle modification, but has been unable to quit smoking. His clinic values have been similar and averaged 150/95 mm Hg for the past 3 months. Clonidine 0.1 mg twice daily is added to his regimen. What problems might occur if T.M. is not adherent with clonidine therapy?

α_2-Agonists are most effective when used with a diuretic because they all can cause fluid retention. Ideally, they should be used with agents that have different mechanisms of action and with agents that do not affect other central adrenergic receptors. Clonidine can cause rebound hypertension when abruptly stopped. T.M.'s occupation may place him at risk for this complication if he misses doses because of unusual work hours or prolonged travel.

CASE 9-11, QUESTION 2: How should T.M.'s clonidine dose be titrated?

Clonidine should be started at a low dosage and gradually increased to achieve optimal BP lowering with minimal side effects. The immediate-release tablet is started as 0.1 mg twice daily, with 0.1- or 0.2-mg/day increases every 2 to 4 weeks until his BP goal is achieved or side effects appear. Clonidine is also available as an extended-release tablet and as a transdermal patch. The patch formulation releases drug at a controlled rate for 7 days and may have fewer side effects than the oral dosage form. The onset of initial BP effect may be delayed for 2 to 3 days after application; thus, rebound hypertension might occur when oral clonidine is switched to transdermal. To prevent this, an oral dose should be taken on the first day that the transdermal patch is used. Anticholinergic side effects, such as sedation and dry mouth, are the most frequent and bothersome side effects of clonidine. These are especially problematic in elderly patients.

CASE 9-11, QUESTION 3: After several months, T.M.'s BP is 148/84 mm Hg with clonidine 0.2 mg twice daily. However, he is now experiencing daytime somnolence and dry mouth. What other α_2-agonists are available?

Methyldopa

Methyldopa has been extensively evaluated and is considered safe in pregnancy. Therefore, it is recommended as a first-line agent when hypertension is first diagnosed during pregnancy.[111] Beyond that, little role exists for methyldopa in the management of hypertension. The usual initial dose is 250 mg administered twice daily up to 2,000 mg/day. Methyldopa causes side effects similar to those associated with clonidine, including sedation, lethargy, postural hypotension, dizziness, dry mouth, headache, and rebound hypertension. These may decrease with continued use. Other significant side effects include hemolytic anemia and hepatitis. Although these are both rare, they necessitate discontinuing the medication.

Others

Guanfacine and guanabenz have a high incidence of side effects. These agents can cause dry mouth, sedation, dizziness, orthostatic hypotension, insomnia, constipation, and impotence. Guanfacine has a long half-life and may have less rebound hypertension than other α_2-agonists. The adverse effects of other α_2-agonists (methyldopa, guanfacine, and guanabenz) are nearly identical to those of clonidine. In general, patients who do not tolerate one α_2-agonist will not tolerate the others. An antihypertensive agent from a different class (aldosterone antagonist, aliskiren, reserpine, or an arterial vasodilator) should be chosen for T.M.

RESERPINE

CASE 9-11, QUESTION 4: Would reserpine be a reasonable option for T.M.?

Reserpine is one of the oldest antihypertensive agents currently available. It is extremely effective in lowering BP when added to a thiazide diuretic. Reserpine is inexpensive and is dosed once daily. Several of the landmark trials that demonstrated reduced morbidity and mortality with BP lowering in hypertension used reserpine. The SHEP trial used reserpine as a second-step agent added to chlorthalidone in patients who could not take atenolol.[88]

Low-dose reserpine (0.05–0.1 mg once daily) is effective at lowering BP and has significantly fewer side effects compared with high doses. Reserpine can cause nasal stuffiness in many patients. Gastrointestinal ulcerations have been reported, but they are associated with either parenteral administration or very large doses. T.M. is a candidate for low-dose reserpine. He is already taking a thiazide diuretic, which should always be used with reserpine, and his therapeutic options are limited. Of all the agents remaining for T.M., other than aliskiren, reserpine has the most favorable side effect profile.

Many clinicians avoid reserpine because of the myth that it can cause depression. This fear was generated from case reports in the 1950s when high doses (0.5–1.0 mg/day) were used. Many of the patients described in these cases would not meet modern criteria for depression; rather, they would be considered oversedated. When reserpine is limited to a maximum of 0.25 mg daily, depression is no more frequent than with other antihypertensive agents.

ARTERIAL VASODILATORS

Hydralazine

CASE 9-12

QUESTION 1: C.M. is a 56-year-old woman with a history of hypertension and severe CKD (estimated GFR of 14 mL/minute/1.73 m^2). Her antihypertensive regimen consists of torsemide 40 mg daily, amlodipine/olmesartan 10/40 mg daily, and metoprolol succinate 200 mg daily. She started hydralazine 25 mg 3 times daily 4 weeks ago when her BPs were 148/92 and 146/90 mm Hg. She has been very compliant, and her BP is now 146/88 mm Hg with a heart rate of 82 beats/minute. Her lung fields are clear, with 1+ bilateral pitting edema. Serum electrolytes are within normal limits. Why was hydralazine used in C.M.?

Hydralazine causes direct relaxation of arteriolar smooth muscle. Arterial vasodilators are infrequently used, except for patients with severe CKD. In this population, hypertension is difficult to control and often requires four or five agents. Severe CKD results in increased renin release and increased fluid retention. Potent vasodilation, in combination with diuresis, is often effective in lowering BP under these conditions. This vasodilation, however, stimulates the sympathetic nervous system and results in a reflex tachycardia, increased PRA, and fluid retention. Thus, the hypotensive effects of direct arterial vasodilators can quickly diminish with time when used as monotherapy. To prevent this, arterial vasodilators need to be used in combination with agent that can slow down heart rate (e.g., β-blocker or nondihydropyridine CCB) to counteract reflex tachycardia, as well as a diuretic (often a loop diuretic if used in severe CKD) to minimize fluid retention.

CASE 9-12, QUESTION 2: After 18 months, C.M.'s hydralazine dose is 50 mg 3 times daily, and her BP is at goal. She now complains of joint pain in both her right and left hands, which extends to the wrists, and generalized weakness with frequent fevers. Laboratory findings for C.M. showed a positive antinuclear antibodies test (diffuse), a white blood cell count of 3,500/μL, and an erythrocyte sedimentation rate of 45 mm/hour, and she is diagnosed with drug-induced lupus (DIL). How should this be managed?

C.M.'s symptoms are consistent with DIL. Hydralazine is one of the most common agents reported to cause DIL. Musculoskeletal pains are the most frequent symptoms, but systemic symptoms and rash may also occur. Hydralazine doses as low as 100 mg/day can cause DIL, and the risk significantly increases when greater than 200 mg/day is used.

Hydralazine should be discontinued. Symptoms should subside within days or weeks, and complete resolution can be expected.

Minoxidil

CASE 9-12, QUESTION 3: What alternatives to hydralazine are available for C.M.?

C.M.'s BP responded to hydralazine, so she would likely benefit from another arterial vasodilator. Minoxidil, a potent arterial vasodilator, is similar to hydralazine with regard to reflex tachycardia, increased CO, increased PRA, and fluid retention. Therefore, concomitant β-blocker and diuretic therapy is still needed. Minoxidil should be reserved for patients such as C.M. who have severe CKD or possibly for resistant hypertension.

CASE 9-12, QUESTION 4: How should C.M. be counseled if minoxidil is started?

Hypertrichosis is a common adverse effect of oral minoxidil, occurring in 80% to 100% of patients. The hair growth is not associated with an endocrine abnormality and begins within the first few weeks. It commonly occurs on the temples, between the eyebrows, on the cheeks, and on the pinna of the ear. Hair growth can extend to the back of the legs, arms, and scalp with continued use. Some patients, especially women, find the hypertrichosis so intolerable that they stop treatment. Topical minoxidil is an approved therapy for male pattern baldness, but topical administration does not provide BP-lowering effects.

Fluid retention with minoxidil is common, presenting as edema and weight gain. If adequate diuresis is not maintained during minoxidil therapy, left ventricular dysfunction may be precipitated or worsened. This also occurs with hydralazine. The compensatory reflex tachycardia with minoxidil may also precipitate angina in patients who have, or are at risk for, CAD.

Peripheral Vascular Disorders

Snehal H. Bhatt and Mary G. Amato

CORE PRINCIPLES	CHAPTER CASES
1 Peripheral arterial disease (PAD) is stenosis or occlusion in the peripheral arteries of the legs, usually caused by atherosclerosis. A sometimes-painful complication called intermittent claudication (IC) can be associated with PAD and is described as aching, cramping, tightness, or weakness of the legs, which usually occurs during exertion.	**Case 10-1 (Question 1)**
2 Treatment for PAD should include therapeutic lifestyle changes and pharmacologic intervention based on risk factors present. Specific interventions may include smoking cessation; exercise; management of dyslipidemia, hypertension, and diabetes; antiplatelet therapy; and verapamil.	**Case 10-1 (Questions 2–11)**
RAYNAUD PHENOMENON (RP)	
1 RP is an exaggerated vasospastic response to cold or emotion, likely mediated through sympathetic response to the precipitating stimuli. RP is classified as primary or secondary, in which secondary causes include connective tissue diseases and occupational-related neural damage.	**Case 10-2 (Question 1)**
2 Treatment for RP should include therapeutic lifestyle changes and pharmacologic intervention based on clinical presentation and underlying etiology. First-line interventions may include avoidance of cold stimuli and medications associated with vasoconstriction and treatment with calcium-channel blockers (CCBs). Several other therapies may be emerging as possible therapeutic options, including renin–angiotensin–aldosterone inhibitors, topical nitroglycerin, statins, peripheral α-adrenergic blockers, intravenous prostanoids, endothelin antagonists, and oral phosphodiesterase inhibitors.	**Case 10-2 (Questions 2–4)**
NOCTURNAL LEG MUSCLE CRAMPS	
1 Nocturnal leg muscle cramps are idiopathic, involuntary contractions occurring at rest that cause a visible and palpable knot in the affected muscle, usually occurring in the early hours of sleeping.	**Case 10-3 (Question 1)**
2 The primary treatment goal of nocturnal leg muscle cramps is the prevention of episodes. Recommendations include stretching practices, alteration of sleeping position, and treatment of modifiable causes (i.e., electrolyte abnormalities).	**Case 10-3 (Questions 2–4)**

PERIPHERAL ARTERIAL DISEASE

Peripheral arterial disease (PAD) is a common and sometimes painful complication from stenosis or occlusion in the peripheral arteries of the legs, usually caused by atherosclerosis. Similar to coronary artery disease (CAD) resulting in chest pain, PAD pain can be classified as “angina” of the legs. When closely comparing the risk factors and pathology of both diseases, the association with CAD and IC becomes clear.

IC is described as aching, cramping, tightness, or weakness of the legs which usually occurs in the calves during walking and is relieved at rest. Tissue ischemia, resulting numbness or continuous pain in the toes or foot, may be present and can lead to ulceration. IC is a painful condition that can severely limit mobility and lead to tissue necrosis or amputation of the affected limb. Many patients with PAD, however, are asymptomatic or have atypical lower limb symptoms, such as leg fatigue, difficulty walking, or similar nonspecific complaints. Patients may not seek medical attention until the condition is advanced because of the gradual onset of symptoms associated with IC.

Table 10-1

Annual Incidence of Intermittent Claudication by Age[3]

Age Group (years)	Annual Incidence (%)
40–49	2.0
50–59	4.2
60–69	6.8
70	9.2

Epidemiology

PAD is a relatively common condition that affects men and women equally, with a prevalence of 12%,[1] although men have a twofold increased prevalence of symptomatic IC.[2] The annual incidence of IC increases dramatically with age (Table 10-1). Most patients with PAD are asymptomatic. In one study where the prevalence of IC symptoms was 2%, only 11.7% of patients had detectable large vessel atherosclerosis of the lower extremities.[3] This disparity between IC symptoms and the presence of PAD contributes to the observation that 50% to 90% of patients with IC do not mention PAD symptoms to their physician. Patients attribute the symptoms of IC to normal walking difficulties associated with aging, not a medical condition requiring treatment.[4] Public knowledge of the definition of PAD, risk factors for the development of the disease, associated symptoms and disease states, and amputation risk were evaluated in adults older than 50 years of age in a cross-sectional, population-based telephone survey. Unfortunately, only 25% of the population reported awareness of PAD.[5]

Risk factors for developing occlusive PAD are similar to those for CAD. Long-standing diabetes is the most significant risk factor, with 30% of patients with diabetes affected by PAD.[6] Each 1% increase in glycosylated hemoglobin is associated with a 28% risk of incident PAD.[7] Other atherosclerotic risk factors associated with PAD include cigarette smoking, hypertension, and dyslipidemia.[8] Hypertriglyceridemia is a more significant risk factor for PAD than for CAD, and this may partially explain the increased prevalence of PAD in patients with diabetes.[9]

Cigarette smoking is the strongest risk factor for PAD and the development of IC pain than any other risk factors, and the risk increases dramatically with the duration of smoking history and number of cigarettes smoked per day.[10] In patients with hypertension or diabetes, smoking further increases the rate of claudication development. Smoking confers a sevenfold increase in risk for PAD compared with not smoking.[11]

Epidemiologic studies following PAD patients over 4 to 9 years show that IC is nonprogressive in 75% of patients, whereas 25% of patients with IC will have worsening painful ischemic episodes. Ischemic tissue changes, ulceration, and gangrene can accompany advanced PAD. Amputation of the affected limb is rare, but can occur in up to 5% of patients with claudication.[12] The presence of two independent risk factors, such as diabetes and cigarette smoking, has an additive effect on the risk for the development of progressive IC and serious limb complications (Table 10-2). Finally, disease location in patients with severe disease may be associated with prognosis. Proximal disease may be associated with poor outcomes when compared with distal lesions, although further studies are needed to confirm these findings.[14]

Table 10-2

Long-Term Incidence of Outcomes in Patients with Intermittent Claudication[12,13]

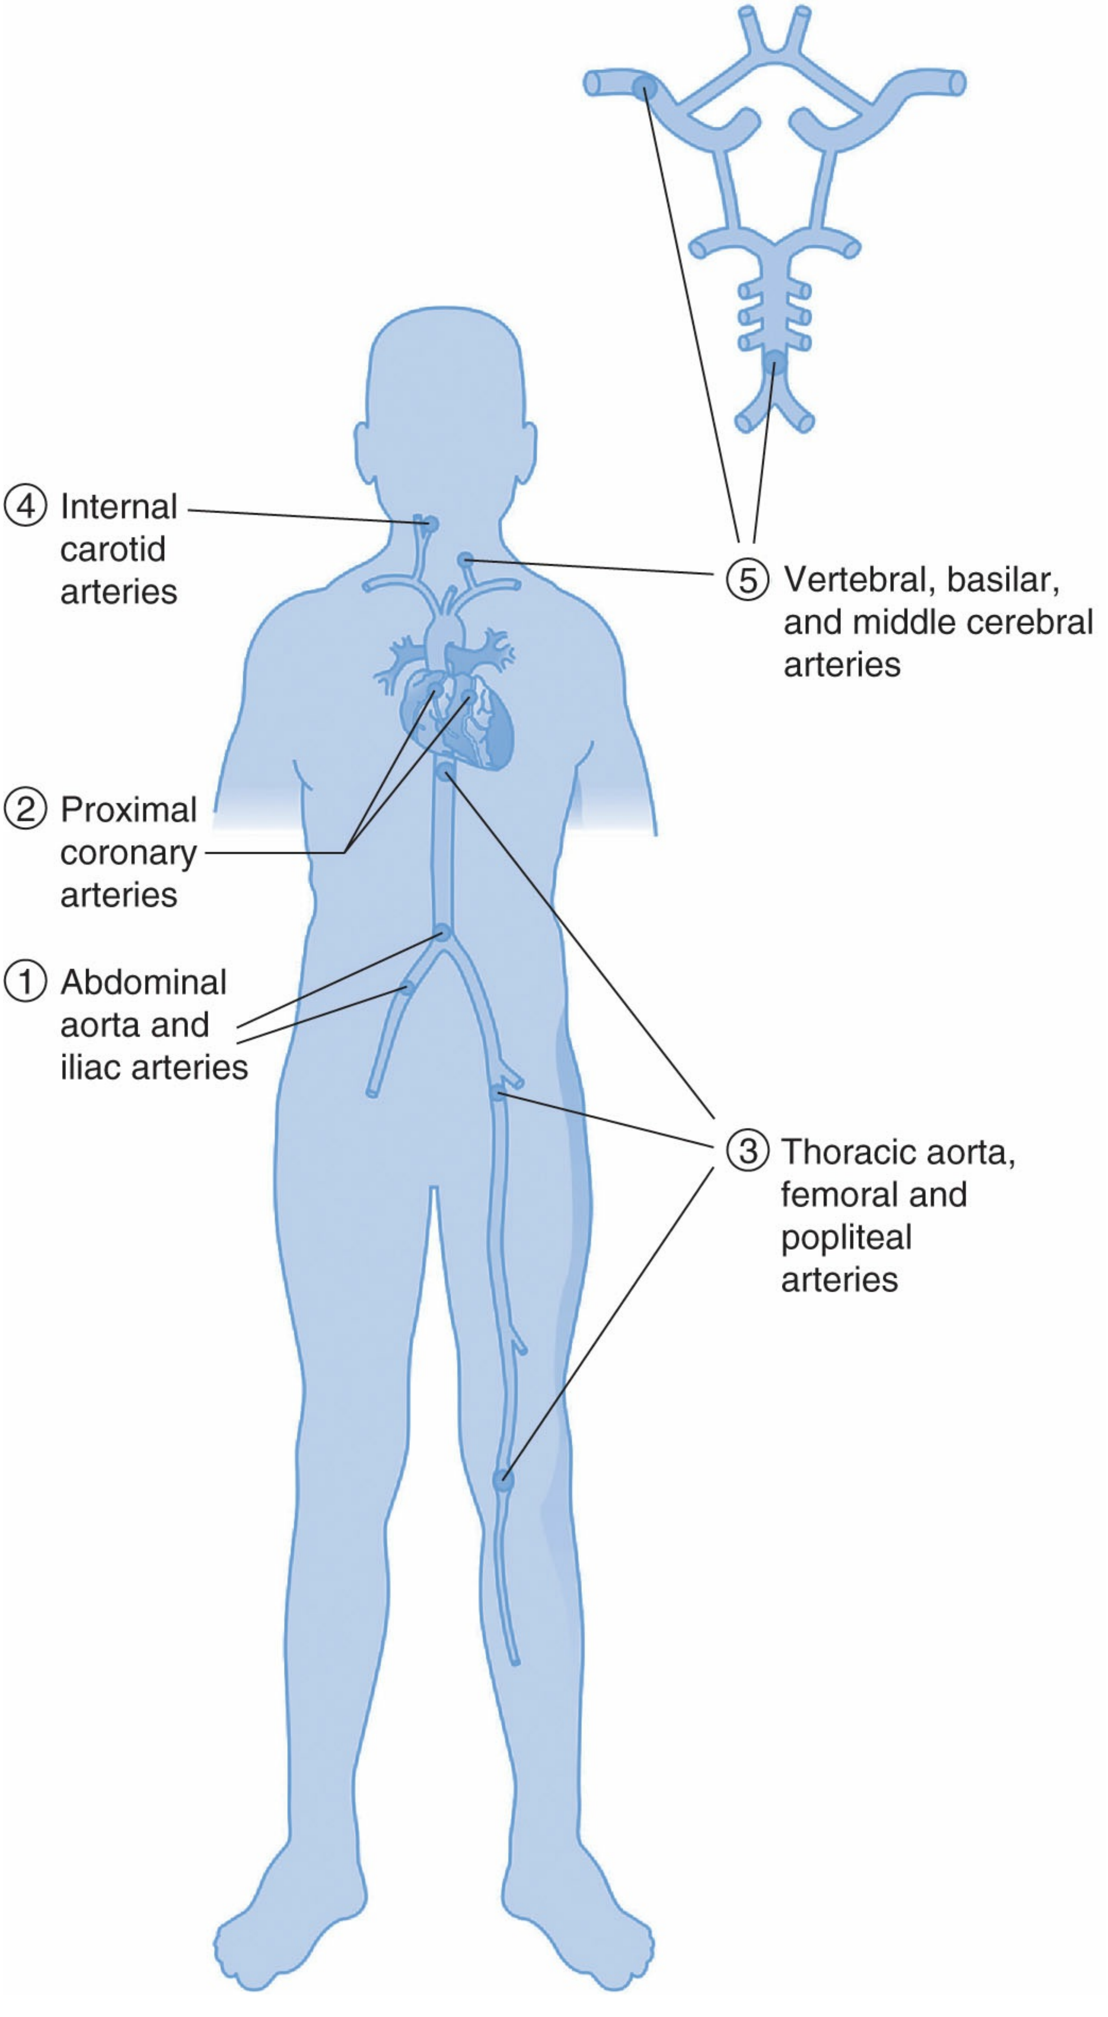
Patient Population	Abrupt Limb Ischemia (%)	Amputation (%)
All patients	23	7
Diabetes	31	11
Smokers	35	21

During a relatively short 2-year follow-up of patients with IC, 3.6% of patients died, whereas 22% experienced a nonfatal cardiovascular event (defined as any cardiac, cerebral, or peripheral vascular event). Walking capacity declined in 26%

during the same time frame, thus it is paramount to recognize that severe, short-term morbidity is highly likely in this patient population.[13,15]

Pathophysiology

IC is the predominant complication of occlusive PAD because of the resulting pain and subsequent decreased mobility. The major cause of occlusive PAD is arteriosclerosis obliterans, defined as the development of atherosclerotic plaques in the peripheral vasculature. These plaques develop as a result of endothelial activation in association with conditions such as dyslipidemia, diabetes mellitus, hypertension, and smoking. Plaques also result from the proliferation of vascular smooth muscle, with subsequent damage to the vascular structure. This damaged endothelium has impaired vasodilatory capabilities because secretion of nitric oxide is decreased and secretion of vasoconstrictive substances, such as endothelin, is increased, impeding blood flow to the extremities. Further growth of atherosclerotic lesions can physically limit blood flow. Exercise may induce IC symptoms in patients who have lesions with greater than 50% stenosis, whereas patients with lesions of greater than 80% stenosis can have pain at rest. The lesions themselves can become unstable and rupture, or adjacent smaller vessels experiencing high hemodynamic pressure caused by nearby plaques may rupture as well. Either situation can lead to acute vascular occlusion, analogous to unstable angina or acute myocardial infarction (MI) in coronary arteries.[16]



④ Internal carotid arteries
⑤ Vertebral, basilar, and middle cerebral arteries
② Proximal coronary arteries
① Abdominal aorta and iliac arteries
③ Thoracic aorta, femoral and popliteal arteries

Figure 10-1 Sites of severe atherosclerosis in order of frequency. (Adapted with permission from Rubin R et al. Rubin's Pathology: Clinicopathology Foundations in Medicine. 6th ed. Philadelphia, PA: Wolters Kluwer, Lippincott Williams & Wilkins; 2012:452.)

Figure 10-1 illustrates the common sites of atherosclerosis. Plaques that develop in central vessels (e.g., in the aorta and iliac artery) are primarily associated with buttock pain and erectile dysfunction. Those confined to the more distal femoral and popliteal arteries characteristically cause thigh and calf pain. Occlusion of the tibial arteries will produce claudication pain in the foot. When more than one arterial bed is affected by severe atherosclerosis, symptoms of IC will be diffuse. Symptoms of IC indicate an inadequate supply of arterial blood to peripheral muscles. Exercise, including walking, increases the metabolic demands of the muscles and can lead to claudication pain.

Erythrocyte deformability is an important factor for in vitro capillary perfusion.[17,18] In areas without compromised blood flow, normal red blood cells (RBCs) have the ability to deform when passing through a small capillary. By aligning themselves in a planar manner, RBCs reduce viscosity of the blood suspension, enabling them to pass smoothly through capillaries. In many patients with IC, RBCs have a marked decreased ability to deform, resulting in increased blood viscosity. This defect is promoted by chronic tissue ischemia and hypoxia caused by increased intracapillary leukocyte adherence, platelet aggregation, and activation of complement and clotting factors.[16] The vascular responses to hypoxia are detrimental because this sequence of events further inhibits blood flow and oxygen delivery to the tissues (Fig. 10-2).

Clinical Presentation

CASE 10-1

QUESTION 1: R.L. is a 60-year-old, 110-kg man with a history of type 2 diabetes mellitus, chronic stable angina, dyslipidemia, and smoking. His chief complaint today is right upper thigh pain while walking around the block. The pain has gradually increased during the past 12 months, but only recently has become intolerable. The pain is relieved within minutes after he stops walking. R.L. smokes 2 packs of cigarettes a day.

His most recent laboratory results are significant for the following results:

Total cholesterol, 290 mg/dL (SI units, 7.49 mmol/L)
Fasting triglycerides, 350 mg/dL (SI units, 3.95 mmol/L)
Low-density lipoproteins (LDL), 188 mg/dL (SI units, 4.86 mmol/L)
High-density lipoproteins (HDL), 32 mg/dL (SI units, 0.83 mmol/L)
Serum creatinine (SCr), 0.8 mg/dL (SI units, 61 mmol/L)
Blood urea nitrogen (BUN), 18 mg/dL (SI units, 6.4 mmol/L)
Hemoglobin (Hgb) A_{1c}, 10.5% (SI units, 91.3 mmol/mol)
Fasting glucose, 190 mg/dL (SI units, 10.5 mmol/L)
Blood pressure (BP), 170/95 mm Hg

Heart rate (HR), 89 beats/minute

His posterior tibial artery pulse is not palpable. A Doppler ultrasound study is performed, and his ankle-to-brachial index (ABI) is 0.7 (normal, >0.90).

R.L.'s medication list includes isosorbide mononitrate 60 mg daily, aspirin 81 mg daily, and ramipril 5 mg daily. His insulin doses have progressively increased to neutral protamine Hagedorn (NPH) insulin 40 units in the morning and 35 units in the evening. What risk factors and elements of R.L.'s presentation are consistent with a diagnosis of IC?

R.L.'s medical history illustrates classic risk factors for vascular occlusion and IC, including dyslipidemia, diabetes, hypertension, and smoking. His diabetes is not adequately controlled based on elevated Hgb A_{1c} and fasting glucose levels, and he is obese. This constellation of disorders is known as the metabolic syndrome. These factors, along with smoking, are commonly seen together and have been linked with insulin resistance and accelerated atherosclerosis (Fig. 10-3).[19,20] The presence of angina indicates CAD, so it is not surprising that he has peripheral vascular occlusion as well.

Atherosclerotic Plaque
Platelet Aggregation

Figure 10-2 Erythrocyte inflexibility in intermittent claudication.

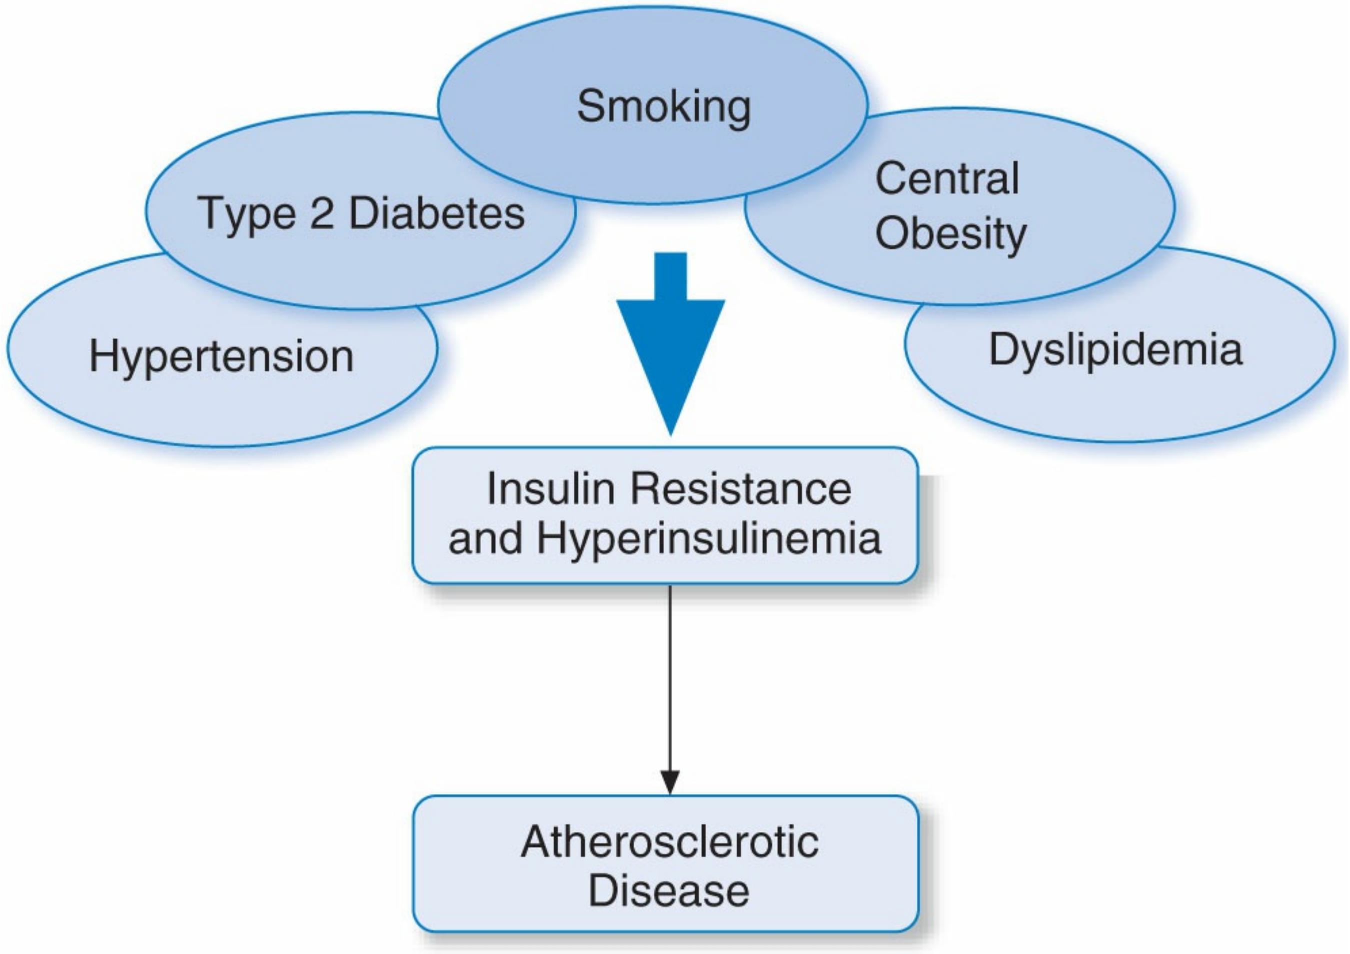

Figure 10-3 The metabolic syndrome in atherosclerosis.

The classic pain of IC described by R.L. is associated with exercise of the affected muscle group(s) and subsides with a few minutes of rest. Other common symptoms of extensive atherosclerosis include cold feet and persistent aching of the feet during rest or sleep. Restricted blood flow to the feet along with pooling of blood secondary to inadequate pressure needed to propel blood back up the leg can lead to rubor (red or purple color of the foot). Other indicators of peripheral atherosclerosis are the loss of hair from the top of the feet, thickening of the toenails, and absence of sweating of the lower legs and feet, all caused by poor circulation.[16]

The results of objective studies performed on R.L. are consistent with IC. Doppler ultrasound of the spine is helpful in excluding pseudoclaudication caused by spinal stenosis and other neurogenic or musculoskeletal causes of leg pain. Ultrasound is also useful to measure BP of the lower extremities. An ABI of 0.7 means that the ankle systolic BP reading is only 70% of the systolic pressure in the brachial artery supplying blood to the arm. In patients with IC, this is caused by atherosclerotic obstruction of blood flow in the lower limbs and subsequent decreased perfusion pressures in the ankle compared with the arm (Table 10-3). As the ABI decreases, blood flow to the extremities is reduced and the severity of symptoms is greater. An ABI less than 0.9 is diagnostic for PAD. Loss of the posterior tibial pulse, as seen in R.L., is common in those with peripheral vascular occlusion.

Table 10-3

Severity of Arterial Obstruction as Assessed by Ankle-to-Brachial Index[21]

Severity	Ankle-to-Brachial Index[a]
Normal	>0.90
Mild	0.70–0.89
Moderate	0.50–0.69
Severe	>0.50

[a] Ankle-to-brachial index is the systolic blood pressure in the ankle divided by the systolic blood pressure in the arm.

Treatment

THERAPEUTIC OBJECTIVES AND NONPHARMACOLOGIC INTERVENTIONS

CASE 10-1, QUESTION 2: What are the therapeutic goals in treating R.L.? What interventions should be initiated to prevent claudication pain and arrest progression of his disease?

Specific treatment goals include preventing further claudication pain, lessening his current pain, arresting the progression of underlying disease, and decreasing his risk of cardiovascular events. Achieving these goals will provide R.L. with the best chance of avoiding further mobility impairment, amputation, and cardiovascular events. An important concept that should be stressed when explaining these treatment goals to R.L. is that all his diseases are closely interrelated and that a beneficial intervention for one disease is beneficial for all. Interventions that can be initiated include diet modification; exercise and weight loss; and attainment of goal BP, lipids, Hgb A_{1c}, and fasting and postprandial blood glucose levels. The American College of Cardiology and American Heart Association (ACC/AHA) have published guidelines that thoroughly evaluate the interventions and medications that have been used to treat IC and PAD.[8] Table 10-4 summarizes these recommendations. The two most important things that R.L. can do for his IC are summed up in five words: “Stop smoking and keep walking.”[23]

Smoking Cessation

The importance of smoking cessation cannot be overemphasized to patients with IC. It is the most important modifiable factor in preventing the development of rest pain, prolonged limb ischemia, need for amputation and reducing the risk for cardiovascular events. Several studies document improved survival and decreased amputation rates in patients with IC who stopped smoking compared with patients who continue to smoke.[24,25] Other benefits, such as improved treadmill walking distance, decreased disease progression, and decreased complications after vascular reconstructive surgery, have been shown in patients who quit smoking compared with patients who continue.[8,24,26–28] It is the one intervention that will decrease R.L.'s claudication pain most rapidly. He will also decrease his risk of MI and mortality by threefold and fivefold, respectively. Table 10-5 summarizes the risk of cigarette smoking and the value of smoking cessation on cardiovascular complications.

Many pharmacologic products and strategies are available to aid R.L. to stop smoking (see Chapter 91, Tobacco Use and Dependence). However, nicotine itself has harmful effects on the vasculature via catecholamine release and vasoconstriction; and it may play a role in endothelial damage and atherosclerosis progression.[29]

Table 10-4

Medical Treatment of Peripheral Arterial Disease and Expected Outcomes[8,22]

Intervention	Improve Leg Symptoms?	Prevent Systemic Complications?
Smoking cessation	Yes	Yes
Exercise	Yes	No
Cilostazol	Yes	No
Statin drugs	Yes	Yes
Angiotensin-converting enzyme inhibitors	Yes	Yes
Blood pressure control	No	Yes
Antiplatelet therapy[a]	No	Yes

[a] Aspirin or clopidogrel.

Table 10-5

Patient Outcomes Based on Smoking Status After Intermittent Claudication Diagnosis[12,24]

Outcome	Length of Follow-Up (years)	Patient Population	
		Current Smokers (%)	Past Smokers (%)[a]
Rest pain	7	16	0
Myocardial infarction	10	53	11
Amputation	5	11	0
Mortality	10	54	18

[a] Quit after intermittent claudication diagnosis.

Exercise

An individualized and supervised exercise program is endorsed for patients with PAD and will benefit most of R.L.'s other risk factors as well.[8] IC pain results in decreased mobility, and because of deconditioning from lack of exercise, patients with IC may slowly become dependent on others for activities of daily living. An exercise program is the most effective way to both preserve and increase mobility. It is more effective than the best pharmacologic therapy currently available.[30] The ideal exercise program consists of walking for a minimum of 30 to 45 minutes at least 3 times a week, for a minimum of 12 weeks.[8] R.L. should walk as fast and far as he can until the pain becomes severe; he should then wait until the pain subsides, and then resume walking.[21] At first, R.L. may experience several painful episodes during each exercise session, but these should gradually decrease as the beneficial effects of exercise therapy begin to emerge. Studies have documented that this type of exercise program can more than double the pain-free distance a patient with IC is able to walk.[31] Lower extremity resistance training can provide improved functional performance measured by the following: quality of life, treadmill walking time, and ability to climb stairs.[32] An appropriate exercise program results in superior outcomes compared with angioplasty and stenting, and equal in terms of walking distance compared with surgery, but without any of the significant complications and mortality associated with surgery.[31]

Rheologic abnormalities of increased blood viscosity, impaired RBC filterability, hyperaggregation, and polycythemia (elevated hematocrit) have been shown to return to normal in many patients with IC who participate in a regular exercise program.[33] Exercise may offset the need for pharmacologic intervention. The potential mechanisms by which exercise benefits patients with IC are listed in Table 10-6.

Dyslipidemia Management

CASE 10-1, QUESTION 3: Is lipid-lowering therapy indicated for R.L.?

Because IC is a consequence of atherosclerosis, arresting the progression of R.L.'s atherosclerotic disease is important (see Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease). Initiation of the nutritional and exercise recommendations should be recommended as outlined in 2013 ACC/AHA Lifestyle Management to reduce cardiovascular risk guidelines[34] and endorsed by the ACC/AHA Guideline on the treatment of blood cholesterol to reduce atherosclerotic cardiovascular risk in adults.[35] Therapeutic lifestyle changes and cholesterol-lowering agents are the cornerstones for attaining this goal. Considerable data suggest that aggressive dietary and pharmacologic management of dyslipidemia, particularly lowering low-density lipoprotein cholesterol (LDL-C), leads to regression of atherosclerotic lesions in the coronary and carotid vasculature.[36–38] In contrast, relatively few prospective data exist about the effect of successful lipid-lowering therapy on the regression or stabilization of peripheral lesions, or on clinical events in patients with PAD. A post hoc analysis of a large lipid-lowering study in subjects with known CAD treated with simvastatin demonstrated a significant decrease in new or worsening IC, suggesting that in high-risk patients, lipid lowering can prevent development of clinically symptomatic PAD.[39] The Heart Protection Study randomly assigned patients with known arterial disease of various types to simvastatin 40 mg daily or placebo. After 5 years, a 15% decrease was found in noncardiac revascularizations, including amputations, among the patients receiving simvastatin.[40] Short-term outcomes (e.g., 6 months to 1 year), such as improved walking distance and walking time, have also been documented with simvastatin 40 mg/day.[41,42]

Table 10-6

Primary Mechanisms of Symptom Improvement with Exercise Therapy in Intermittent Claudication[30]

- Decrease of blood viscosity
- Metabolic changes in the muscle
  - Improved muscle metabolism
  - Improved oxygen extraction
- Improved endothelial function and microcirculation
- Decreased occurrence of ischemia and inflammation
- Atherosclerosis risk factors improved via
  - Weight loss
  - Glycemic control
  - Blood pressure control
  - Increased high-density lipoprotein (HDL)
  - Decreased triglycerides
  - Decreased thrombotic tendency

A meta-analysis of 10,049 subjects from several randomized trials using a variety of lipid-lowering therapies in patients with PAD demonstrated reduced claudication severity and decreased disease progression as measured by angiography. A decrease in mortality did not reach statistical significance.[43] Limited data suggest high apolipoprotein [Lp(a)] concentrations may be particularly important in the development of PAD.[44]

Patients with PAD fall into one of the four major statin benefit groups, specifically falling into the group with known atherosclerotic cardiovascular disease (ASCVD). Since R.L. is less than 75 years old, he warrants high-intensity statin therapy, which is defined as statin therapy at doses that are expected to provide at least a 50% reduction in LDL cholesterol (see Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease). There is a paucity of outcome data with other agents for dyslipidemia, as recent trials of omega-3 fatty acid, niacin, or fibric acid derivative have failed to demonstrate a reduction in cardiovascular events in patients with increased risk for cardiovascular events like R.L.[8,45–48]

Management of Hypertension

CASE 10-1, QUESTION 4: R.L.'s BP is elevated to 170/95 mm Hg despite ramipril therapy. Because he has angina, and his HR is 89, a β-adrenergic blocker is considered. Are there alternative antihypertensive therapies that might be preferable for R.L.?

R.L.'s hypertension has likely contributed to the development of his atherosclerosis and PAD. Hypertension (see Chapter 9, Essential Hypertension) has been associated with deficiencies in the synthesis of vasodilating substances, such as prostacyclin, bradykinin, and nitric oxide, by the endothelial cells lining the vasculature, along with increases in vasoconstricting substances like angiotensin II. Increased vascular tone can alter local hemodynamics, especially in the presence of a stenotic lesion. Although it has not been determined whether normalization of BP has a positive effect on IC, it is well established that uncontrolled BP results in vascular complications such as MI and stroke. In light of R.L.'s numerous risk factors for these complications, improvement in his BP is warranted.

β-Blockers are frequently cited as contraindicated in IC patients owing to the potential for unopposed α-adrenergic-mediated vasoconstriction during peripheral β-blockade. However, evidence to document worsening IC by β-blockade is lacking. Overall, controlled studies have been inconclusive and a meta-analysis of placebo-controlled trials and studies with control groups concludes that β-blockers do not worsen claudication.[49,50]

Angiotensin-converting enzyme (ACE) inhibitors are first-line agents in patients with PAD.[8] Compared with other antihypertensive agents, the data available support their beneficial effects in this population. Compared with placebo, walking distance is increased with both perindopril and ramipril in patients with PAD.[51,52] The Heart Outcomes Prevention Evaluation (HOPE) study compared ramipril versus placebo in over 9,000 patients who had evidence of vascular disease or diabetes. Impressively, they enrolled more than 4,000 patients with PAD, and similar to the overall trial population, patients with PAD derived a benefit in the composite endpoint of decreased mortality, MI, and stroke.[53] The ONTARGET trial compared telmisartan, ramipril, and the combination of the two in patients with vascular disease or high-risk diabetes without heart failure for a composite end point of cardiovascular death, MI, stroke, or hospitalization for heart failure. The results suggested equivalency of telmisartan to ramipril for the primary end point with similar BP reduction in both groups; however, the combination therapy group experienced more adverse events without any benefit.[54] Based on these data, ARBs may be a suitable substitute for ACE inhibitors, but combination therapy is not recommended.

R.L.'s. BP goal is less than 140/90 mm Hg.[55–57] His dose of ramipril could be increased, or a low-dose diuretic, such as hydrochlorothiazide or chlorthalidone,[55,56] could be added. Given his history of chronic stable angina, the addition of a CCB or a β-blocker would be an option as well. The ACCOMPLISH trial compared the combination of benazepril–amlodipine with benazepril–hydrochlorothiazide in patients with hypertension who were at high risk for cardiovascular events. Amlodipine therapy reduced cardiovascular events compared with hydrochlorothiazide, even though BP control was not significantly different.[58] While β-blockers are typically used in patients with CAD, the outcome data supporting their use are less clear.[59]

Management of Diabetes

CASE 10-1, QUESTION 5: Will improving R.L.'s diabetes control or slow the progression of his PAD? What changes in his diabetes management do you recommend?

Patients with type 2 diabetes mellitus (see Chapter 53, Diabetes Mellitus) are able to minimize macrovascular and microvascular complications of their disease with aggressive glucose control.[7,60,61] Insulin, sulfonylurea, or metformin therapies have a beneficial effect on slowing the development of the microvascular complications of diabetes, such as retinopathy and nephropathy. Metformin has specifically been shown to further reduce the occurrence of macrovascular complications such as stroke or MI compared with insulin or sulfonylureas in obese patients with type 2 diabetes.[60]

Table 10-7

Effect of Diabetes Mellitus on Intermittent Claudication Outcomes After 5 Years[11]

	Patients With Diabetes (%)	Patients Without Diabetes (%)
Mortality	49	23
Major amputation	21	3
Deterioration	35	19

R.L.'s diabetes is a significant risk factor for progression to further ischemic events (Table 10-7). He has a twofold greater risk of death and a sevenfold greater risk of amputation compared with a patient without diabetes. Although a specific benefit for IC has not been demonstrated, it seems prudent to initiate or continue aggressive diabetes management in patients with type 2 diabetes mellitus and IC. The addition of metformin to R.L.'s therapy could improve his blood glucose control and decrease his risk of vascular complications. It is hoped that R.L. can reach his Hgb A_{1c} goal of less than 7% and a fasting blood glucose of 80 to 130 mg/dL and 2-hour postprandial glucose of less than 180 mg/dL with diet and exercise, while adding metformin to his current therapy.[62,63]

R.L. also must take proper care of his feet to prevent ulcerative complications of IC. He should be encouraged to keep his feet warm, dry, and moisturized and to wear properly fitted shoes and perform daily foot inspections.[8] He should seek medical attention immediately for minor trauma to his feet or legs.[4] These measures can reduce the incidence of amputation in patients with diabetes.

PHARMACOLOGIC THERAPIES

Antiplatelet Therapies

CASE 10-1, QUESTION 6: Is R.L.'s aspirin therapy beneficial for preventing further complications of IC? Would alternative antiplatelet therapies offer advantages over aspirin?

Aspirin is one of several antiplatelet agents that may be considered for indefinite use in patients with PAD. There is limited data on the effects of aspirin on IC symptoms. Whether aspirin has any beneficial effects on walking distance or claudication pain has not been studied. Available data address the impact of aspirin on overall cardiovascular morbidity and mortality. Although aspirin has no direct effect on plaque regression, it does prevent and retard the role platelets play in the thrombogenic events that occur in the vicinity of atherosclerotic plaques.[64] Aspirin is an effective antithrombotic agent at dosages ranging from 50 to 1,500 mg daily. The lowest dosages proven to decrease cardiovascular events are 75 to 100 mg daily,[65] with the higher dosage showing benefit in active processes, such as acute ischemic stroke[66] and acute MI.[67] A dosage of 75 mg daily has demonstrated benefit in patients with hypertension[68] and stable angina.[69] No evidence indicates that these "low doses" are any more or any less effective than dosages of 900 to 1,500 mg daily.[70]

Aspirin is recommended in patients with vascular disease of any origin (this includes stroke, MI, PAD, and ischemic heart disease). At dosages of 75 to 162 mg/day, aspirin decreases vascular death by approximately 15% and all serious vascular events (MI, stroke, or vascular death) by approximately 20% in high-risk patients, including those with PAD.[62,65,69] In patients with PAD, aspirin can delay the progression of established lesions as assessed by angiography. When used for primary prevention of cardiovascular disease in men, aspirin decreased the need for arterial reconstructive surgery, which was needed because of PAD.[71] In a meta-analysis of 5,269 subjects with PAD, aspirin was associated with a significant reduction in nonfatal stroke with a statistically insignificant decrease of cardiovascular events.[72] However, in a recent large randomized,

controlled trial in 3,350 patients 50 to 75 years of age without clinically evident cardiovascular disease but with a screening ABI of 0.95 or less, aspirin 100 mg/day was found to be no more effective than placebo in reducing the primary end point of fatal and nonfatal coronary events, stroke, or revascularization (13.7 events per 1,000 person-years in the aspirin group versus 13.3 in the placebo group; hazard ratio, 1.03; 95% confidence interval, 0.84–1.27).[73]

Because all dosages of aspirin are similarly efficacious in decreasing vascular events in this patient population, side effects influence the dose chosen. Although few studies have directly compared varying doses, side effects appear to be dose related. Aspirin 30 mg daily results in less minor bleeding compared with approximately 300 mg daily,[74] and 300 mg daily results in fewer gastrointestinal (GI) side effects compared with 1,200 mg daily.[75] Therefore, R.L. should take the lowest effective dose of aspirin: 75 mg to 100 mg daily. Of note, R.L.'s hypertension should be controlled before initiating aspirin therapy to decrease the small increased incidence of cerebral hemorrhage associated with its use.[76]

Ticlopidine is a thienopyridine derivative that blocks adenosine 5′-diphosphate (ADP) receptors on platelets and decreases platelet–fibrinogen binding.[77] Several studies document its efficacy in patients with PAD on end points such as walking distance, cardiovascular death, and the need for revascularization surgery.[78,79] However, hematologic toxicities (neutropenia and, rarely, thrombotic thrombocytopenic purpura) limit its use.[80,81]

Clopidogrel initially replaced ticlopidine largely because of its improved safety profile. The effects of clopidogrel on specific PAD outcomes are unknown, but it has been compared with aspirin in patients with known atherosclerotic disease. Dosages of 75 mg daily significantly reduced cardiovascular end points by approximately 25% compared with aspirin in this patient population.[82] The treatment effect was most pronounced in the PAD subgroup, leading to the suggestion that clopidogrel may be preferable in the patient population with PAD. No measure was taken of clopidogrel's effect on walking distance or claudication pain, however, and these results have not been confirmed by further studies.

The combination of aspirin and clopidogrel was compared with aspirin alone in more than 15,000 patients at high risk of vascular events, of whom greater than 20% had a history of PAD and approximately 10% had IC.[83,84] In this large study that assessed cardiovascular end points, no benefit was found for dual antiplatelet therapy with aspirin plus clopidogrel.[80] Thus, while clopidogrel has the same guideline recommendation as aspirin,8 clinically it is often used as an appropriate alternative to aspirin in patients unable to take aspirin therapy,[65] perhaps owing to a serious allergy.[8] It should not be used in addition to aspirin, however, because the risk of bleeding and increased cost outweigh any measurable vascular benefit.[84,85]

Ticagrelor was compared with clopidogrel in 13,885 patients with known symptomatic PAD but without documented CAD.[86] There was no difference between the two groups with regards to the primary composite endpoint of death, myocardial infarction and stroke. Based on these data, ticagrelor cannot be recommended to reduce the risk of cardiovascular events in PAD patients at this time. These data also question whether there are differences in cardiovascular risk in patients with both

CAD and PAD versus those with PAD alone.

Cilostazol

CASE 10-1, QUESTION 7: Are there any medications that can be used to increase the walking abilities of patients with IC?

Cilostazol is one of the few agents approved by the US Food and Drug Administration (FDA) specifically for the treatment of IC. Several studies have confirmed that cilostazol 100 mg twice daily increases walking distance by approximately 50%[87–90] and that discontinuation of cilostazol results in a decline in function.[91] Cilostazol possesses antiplatelet and vasodilatory effects mediated by the inhibition of phosphodiesterase III.[92] In vitro observations suggest that these pharmacologic effects of cilostazol are particularly pronounced at the blood–vessel interface,[92] which may explain its particular efficacy in the patients with PAD. Studies that included quality-of-life measurements have found that cilostazol improved overall quality of life.[87,93] Small improvements in ABI with chronic cilostazol therapy have also been observed.[94] Two small studies indicate cilostazol is associated with a reduction in restenosis after endovascular therapy in femoropopliteal lesions.[95,96]

Despite these positive findings with cilostazol, several drawbacks exist. It is contraindicated in patients with heart failure based on data with other phosphodiesterase inhibitors demonstrating excess mortality, presumably due to increased arrhythmias.[97] Other common side effects include headache, occurring in up to one-third of patients, and loose stools or diarrhea.[88,98] Cilostazol is a cytochrome P-450 3A4 substrate; therefore, any inhibitor of this enzyme system may substantially increase cilostazol concentrations.

Cilostazol is an important advancement in the treatment of IC. It is the first pharmacologic agent to demonstrate a consistent effect on a significant source of IC disability: walking and mobility measures. While limited data address its impact on other important end points, such as amputation and revascularization procedures or cardiovascular events,[99] it should be added to R.L.'s existing medication regimen at a dosage of 100 mg twice daily to attenuate his symptoms of IC.

Rheologic Agents

CASE 10-1, QUESTION 8: Has pentoxifylline been shown to be efficacious in patients such as R.L.? How does this drug benefit patients with IC?

Pentoxifylline, a methylxanthine derivative, is another agent approved by the FDA for the treatment of IC. Pentoxifylline appears to decrease blood viscosity by decreasing fibrinogen, improving the deformability of both red and white blood cells, and eliciting antiplatelet effects, although the exact mechanism of action is unclear.[100]

While the theoretic and in vitro data are unique and positive, data demonstrating its clinical usefulness are controversial. Improvements in walking distances from study to study are unpredictable, and the clinical importance of the sometimes minimal increases in walking distances is not clear (e.g., pain-free walking of approximately 30 m greater than with placebo).[101] Some experts assert that these potential benefits of questionable clinical significance are not worth the expense of drug therapy or the GI side effects.[102]

Pentoxifylline's role in IC therapy is limited. It may have a role in patients who are unable to engage in exercise therapy, or in patients with markedly reduced walking distances, or in whom any small increase in walking distance would greatly improve a patient's activity level.[103] It also may be tried in patients who have not gained the desired benefit from smoking cessation and exercise therapy, and in patients with contraindications, intolerance, or failure of cilostazol. A 2-month trial of pentoxifylline is adequate to determine whether the patient will benefit from therapy.[21] R.L. is not severely debilitated, and the benefits of smoking cessation, exercise therapy, and cilostazol have not been fully realized. Therefore, pentoxifylline should not be added until his response to these well-proven therapies has been determined and the need for further improvement in walking distance is established.

Vasodilators

CASE 10-1, QUESTION 9: R.L. is already taking isosorbide mononitrate for angina. Because IC is made worse by vasoconstriction, should another vasodilating agent be added to treat both his hypertension and IC?

The use of vasodilators for R.L. would at first appear to be a logical pharmacologic intervention to prevent claudication pain. Vasodilators, including isosorbide, directly or indirectly relax blood vessel walls and increase both skin and muscle blood flow as long as cardiac output is maintained. With obstructive arterial disease, however, vessels are sclerotic and unable to further dilate. As a result, healthy vessels dilate to a greater extent than diseased vessels, and blood flow is redistributed (shunted) away from areas that have the greatest need. BP and perfusion paradoxically drop even further in tissues affected by atherosclerosis, resulting in increased pain. If this process produces ischemia, it is known as the steal phenomenon. Thus, while nitrates are not contraindicated in patients like R.L, they may not be as helpful as their mechanism of action may suggest.

Numerous vasodilators (i.e., prostaglandin E_1, prostacyclin, isoxsuprine, papaverine, ethaverine, cyclandelate, niacin derivatives, reserpine, guanethidine, methyldopa, tolazoline, nifedipine) have been used to treat IC. None, however, has convincingly or consistently improved exercise performance, despite earlier beliefs that they were effective.[104,105] Limited data suggest L-carnitine 1 g twice daily may have benefit in walking distance and initial claudication distance.[106] ACE inhibitors are the exception to this rule, as their beneficial effects are likely independent of their vasodilator properties. One small, controlled study demonstrated improvement in walking distance with verapamil, a CCB, compared with placebo in patients with IC.[107] Further studies with verapamil are needed before its use can be recommended.

Smoking cessation, an exercise program, and cilostazol are the interventions that should reduce R.L.'s symptoms of IC to the greatest degree. Verapamil is a moderate cytochrome P-450 3A4 inhibitor and would be expected to increase concentrations of cilostazol. The magnitude of this interaction has not been characterized, nor has its impact on efficacy and bleeding events been assessed. Based on the necessity of cilostazol therapy in R.L., along with the poorly characterized benefits of verapamil in IC and the plethora of other antihypertensive and antianginal agents, avoidance of verapamil is prudent at this time. If additional BP or antianginal effects are needed, β-blockade or amlodipine can be initiated.

OTHER ANTITHROMBOTIC ALTERNATIVES

CASE 10-1, QUESTION 10: If R.L. was deemed as being high risk for a cardiovascular event while on aspirin, what other antithrombotic therapy options could be initiated?

While there is limited data regarding antithrombotic therapy in patients with PAD, recently one new agent has been approved with potential to provide a benefit in reducing cardiovascular events. Vorapaxar is a platelet protease-activated receptor (PAR)-1 antagonist, which inhibits thrombin-mediated plateletand recently received FDA approval for reducing thrombotic cardiovascular events in patients with PAD. The indication approval was based on a recent study, which enrolled 26, 449 patients with stable atherosclerotic vascular disease who were already receiving dual antiplatelet therapy, of which 14% had PAD.[108] The results showed that treatment with vorapaxar reduced the composite primary endpoint of cardiovascular death, MI stroke, although only the incidence of MI was reduced significantly. Importantly, major bleeding was increased significantly in the vorapaxar group, thus the true benefit of the addition of vorapaxar in these patients is unclear at this time.

Ongoing studies with the P2Y12 receptor antagonist ticagrelor and the direct factor Xa inhibitor oral anticoagulants rivaroxaban and edoxaban will further shed light on the risks and benefits of more potent, target-specific agents in patients with PAD.[109,110] The choice of antiplatelet therapy for R.L. in this scenario would be dependent upon what specific cardiovascular event he experienced, as the choice of therapy would be different if R.L. suffered a MI versus an ischemic stroke (see Chapter 12, Chronic Stable Angina and Chapter 13, Acute Coronary Syndrome).

CASE 10-1, QUESTION 11: Three years have passed, and R.L. stopped smoking 6 months ago. His current medications include isosorbide mononitrate 60 mg daily, aspirin 81 mg daily, and ramipril 10 mg daily; carvedilol

6.25 mg twice a day; NPH insulin 55 units in the morning and 40 units in the evening; and atorvastatin 80 mg daily. His symptoms of IC have remained fairly stable until the recent development of a nonhealing ulcer on his toe. What options are there for R.L. if nonpharmacologic and pharmacologic interventions are not sufficient?

Surgical intervention eventually may be necessary for persistent and complicated disease. Because success rates for preventing amputation and postsurgical complications vary from institution to institution, surgery should be considered only for severely ischemic limbs and should be performed in a hospital with a good record of success.[111] Arterial bypass grafting and percutaneous transluminal angioplasty of the femoral or iliac arteries, similar to cardiac revascularization, are two procedures that can be performed. Angioplasty is beneficial in patients with localized disease, especially in the iliac or superficial femoral arteries, and should be considered in patients who truly are incapacitated by their activity limitations.[112] Angioplasty with or without stent deployment, atherectomy, and the use of drug-eluting stents in the peripheral arteries are all options.[8] The more invasive reconstructive arterial (bypass) surgery can be used if diffuse lesions preclude the use of localized angioplasty. The true benefits and pitfalls of these skilled interventions remain unclear.[113]

Emergency surgical intervention may be required if acute, persistent ischemia develops. This is frequently due to thrombosis associated with advanced atherosclerosis, although other causes, such as cardiac emboli, cannot be excluded.[103] Both surgical thrombectomy and localized thrombolytic administration[114] with tissue-plasminogen activator or urokinase have equal success in alleviating acute limb-threatening ischemia.[115,116] After surgical intervention, patients are advised to resume and remain on antiplatelet therapy indefinitely to reduce the risk of future events.

RAYNAUD PHENOMENON

RP is a clinical syndrome caused by episodic vasospasm and ischemia of the extremities in response to cold, emotional, or physical stimuli.[117–122] Episodes include changes in color of the extremities from white, due to vasoconstriction, to blue, signaling tissue hypoxia and then red when reperfusion occurs.[118] It is usually limited to the skin of the fingers, and less often the toes, but can also occur on the nose, cheeks, and ears.[119] Between attacks, the digits may appear cool and moist or normal. In most cases, the ischemia produced by the phenomenon does not have important consequences; however, in severe cases, atrophy of the skin, irregular nail growth, and wasting or ulceration of the tissue pads can occur.[119] Although both IC and RP are disorders of the peripheral arterial circulation, they differ significantly in that IC results primarily from atherosclerotic obstruction, whereas Raynaud disease is caused by vasospasm.

Diagnosis

This disorder can be separated into primary RP, indicating an idiopathic origin, and secondary RP, which consists of signs and symptoms of RP in the presence of an associated disease or condition, most commonly a connective tissue disorder, such as scleroderma (also known as systemic sclerosis), mixed connective tissue disease, rheumatoid arthritis, or systemic lupus

---

erythematosus. Primary RP is more common (89% of patients) and is more likely to occur in younger patients (<30 years), generally presents with less severe symptoms, normal erythrocyte sedimentation rate, negative antinuclear antibodies, and no associated signs of underlying disease. Patients with secondary RP are more likely to have severe disease with painful symptoms which can progress to ulceration or gangrene in extremities if untreated.[119] The diagnosis is generally a subjective one, consisting of clinical signs and symptoms, cold hands, feet, or both without normal recovery after a cold stimulus, emotional stress, or physical stress (such as vibrations) to the extremities.[121,122] In unaffected individuals, a cold provocation should result in some mottling and cyanotic changes in the hands, with recovery once the stimuli are removed. In patients with RP, however, the same cold provocation causes closure of the digital arteries, which produces a sharply demarcated pallor and cyanosis of the digits that persists despite removal of the stimulus.[121]

Epidemiology

In general, the prevalence of RP is about 3% to 5% across several ethnic groups[120]; however, it is higher in some geographically defined populations.[120] It is more common in women than men, is more frequent in non-Hispanic whites, and has a higher prevalence in patients with family members who also experience RP. An onset in the teenage years suggests primary RP, whereas an onset after 30 years of age suggests a secondary cause.[120] Secondary RP is usually associated with a connective tissue disorder, but several other conditions may predispose individuals to its development. These include occupational-related exposures to vibratory machinery (e.g., drills, grinders, chain saws) that cause neural damage,[120] vinyl chloride, or hand trauma.[122–124] Approximately 15% of patients diagnosed with primary RP will go on to develop a connective tissue disorder within10 years.[125]

RP can also be associated with medications, including β-adrenergic blocking agents, ergots, cytotoxic drugs, chemotherapy, amphetamines and other sympathomimetics, and interferon, all of which can induce vasoconstriction.[126–128] Although avoidance of β-adrenergic blocking agents in patients with RP appears prudent, no discernible effect, as measured by skin temperature and blood flow, was found with the administration of both selective and nonselective β-blockers to patients with RP.[129] RP not associated with a connective tissue disorder is often transient and does not interfere with daily activities.[129] The effect of smoking on RP has yielded conflicting results. Overall, there appears to be a negligible effect of smoking on the prevalence of RP and the incidence of attacks, although there is some evidence that the severity of attacks may be decreased with smoking cessation.[130,131]

Pathophysiology

The pathophysiology involved in the exaggerated, abnormally long-lasting vasoconstriction in response to stimuli seen in RP is complex and still not completely understood. Control of blood vessel reactivity involves a balance of mediators released from circulating cells, the vascular endothelium, hormones, and neurotransmitters.[118,122] Cold-induced vasospastic attacks in patients with primary RP involve a heightened vasoconstriction of digital arteries that is mediated by a subset of peripheral α_2-adrenergic receptors.[118,122,132]

Vascular abnormalities noted in RP can include a deficiency of the vasodilator nitric oxide (NO), an increase in endothelial production of the potent vasoconstrictor endothelin-1, and increased activity of the renin–angiotensin system resulting in vasoconstriction induced by angiotensin II.[122] In secondary RP, structural changes resulting from connective tissue disease may cause arterial damage that results in the α_2-adrenoreceptor aberrancy and endothelial injury that stimulates vasoconstriction, platelet activation, and impaired fibrinolysis.[118,122] It is also possible that serotonin receptors play a role in RP. Serotonin agonists have caused decreased finger blood flow, and, conversely, antagonists have increased digital blood flow.[133]

Clinical Presentation

CASE 10-2

QUESTION 1: L.G., a 39-year-old man, presents today with a 4-day history of left hand pain. He notes that the third digit of his left hand is "cold and somewhat blue," especially in the distal area. The other areas of his hand have recovered, but the distal portion of the digit remains cyanotic and numb. He has used acetaminophen and warm-water soaks without success. He is a construction worker who uses his hands "quite a bit" in his work. He has a history of gastroesophageal reflux and has no allergies. His social history is significant for smoking 1.5 packs of cigarettes a day for 19 years. On physical examination, his extremities reveal appropriate sensation of the forearm and hand. Some blue areas are noted on the distal portion on the third phalanx, with no other signs and symptoms. When L.G.'s opposite hand was placed in cold water, several white splotches appeared, and he experienced tingling in this hand as a result of the cold-water exposure. He is diagnosed as having RP. Does L.G. present with primary or secondary RP?

L.G. presents with what is most likely secondary RP owing to one of several potential underlying causes. His clinical presentation is classic for RP, with vasospasm, pallor, and a cyanotic overtone. The diagnosis is confirmed by the cold-water test, which indicates that the vasospastic attack is precipitated by cold exposure. He has a work history that may easily include hand trauma and the use of vibrating machinery, and his age also suggests secondary RP. Because of its association with connective tissue disorders, other laboratory tests such as an antinuclear antibody and erythrocyte sedimentation rate should be checked.

Treatment

NONPHARMACOLOGIC MANAGEMENT

CASE 10-2, QUESTION 2: What conservative measures can be taken with L.G. to prevent or decrease the painful vasospasm of RP?

Most patients with either primary or secondary RP will respond to conservative management to reduce exposure to triggers such as cold and emotional stress.[119] L.G. should be instructed to protect his hands and fingers from exposure by using mittens and insulated wrappers when handling cold drinks, and to protect other parts of his body from cold exposure. He should also try to minimize emotional stress and occupational exposure to vibrating machinery, and avoid medications that can induce vasoconstriction, particularly sympathomimetics, clonidine, serotonin receptor agonists, and ergot preparations.[119,120] He should be encouraged to stop smoking, which may not affect occurrence of attacks but may decrease their severity and provide an overall positive health benefit.[130]

L.G. has new-onset and relatively mild RP. For others who have more severe symptoms and manifestations, especially patients with underlying connective tissue disorders, it is important to immediately and aggressively manage any ulcers that develop on the digits and to be extremely vigilant in detecting infected digits. Rarely, patients who have severe symptoms including ulceration or thrombosis may require surgical intervention such as peripheral sympathectomy, embolectomy, or ulcer debridement.[119,134,135]

CALCIUM-CHANNEL BLOCKERS

CASE 10-2, QUESTION 3: Nifedipine extended-release 30 mg every day is ordered for L.G. What is the rationale for using a CCB in this case?

Drugs can be used to treat primary and secondary RP if it interferes with the patient's ability to work or perform daily activities or if digital lesions develop.

Most proposed treatments for RP are variably effective, and they introduce the risk for significant side effects.[136,137] Drug therapy should always be in addition to nonpharmacologic measures.

Dihydropyridine CCBs decrease calcium ion influx and prevent vascular smooth muscle contraction, especially vascular responses evoked by cold exposure. Nifedipine, a potent peripheral vasodilator, has been studied the most and has become the drug of choice in patients with RP not controlled by conservative measures. In primary RP, 10 or more episodes per week are common. A meta-analysis showed a decrease of 2.8 to 5 attacks per week and a decrease in severity by 33%.[137] Patients with secondary RP experience a similar decrease in attack severity and also achieve a decrease in number of attacks with nifedipine therapy. Because their baseline number of attacks per week often exceeds 20, the relative benefit is not as great as with primary RP, averaging approximately a 25% decrease in weekly episodes.[138] Doses of 10 to 30 mg 3 times daily of immediate-release nifedipine are beneficial,[137,138] although higher doses, if tolerated, may be required for maximal benefit.[137] Most clinicians administer nifedipine as an extended-release formulation to increase convenience and decrease side effects such as dizziness, headache, facial flushing, and peripheral edema, which can occur in up to 50% of patients,[119,122,137] and this practice is supported by clinical studies.[139,140]

Although less thoroughly studied than nifedipine, other vasoselective CCBs, such as amlodipine, felodipine, isradipine, and nisoldipine, decrease the frequency and severity of ischemic attacks.[141–144] Patients who do not benefit from nifedipine likely will not benefit by switching to another CCB. Patients who cannot tolerate the side effects of nifedipine (e.g., peripheral edema, headache) might benefit by switching to another CCB.

L.G. should be warned of the potential side effects with nifedipine therapy, especially dizziness associated with hypotension, and should return in 2 weeks for assessment. A 30-mg daily dose of extended-release nifedipine is a reasonable starting dose. He should be instructed to keep a diary documenting the number of attacks he experiences and details surrounding each attack, such as time course and precipitating factors. In addition to the usual side effects mentioned above, L.G. should be aware that his symptoms of gastroesophageal reflux could worsen with nifedipine therapy, which can cause a decreased lower esophageal sphincter pressure. This side effect should be specifically assessed at his follow-up appointment.

OTHER THERAPEUTIC AGENTS

CASE 10-2, QUESTION 4: What other drugs may be tried if L.G. cannot tolerate the CCB?

Other than CCBs, no proven therapy for RP exists. Many agents, however, have been used based on limited data. The α_1-adrenergic antagonist prazosin, 1 mg 3 times a day, yielded moderate benefit in two-thirds of patients in two small studies.[145,146] Side effects of prazosin are significant at maximal doses and include dizziness, edema, fatigue, and orthostasis. The longer acting α_1-adrenergic antagonist terazosin was evaluated in one small study, and it improved symptomatology as well as objective measures of blood flow.[147] Insufficient data with this class of drugs exist to routinely recommend their initial use in patients with RP. Topical nitrates have been used clinically for several years and newer formulations have recently been studied, but data showing efficacy is limited.[119]

Several therapeutic approaches are being vigorously investigated and show promise as future therapies for RP. These include the intravenous prostaglandin analogs iloprost and alprostadil, which enhance nitric oxide–mediated vasodilation[148]; endothelin antagonists, such as bosentan[149]; and oral phosphodiesterase inhibitors[150–152] which also promote vasodilation. A meta-analysis of phosphodiesterase inhibitors for the treatment of secondary RP showed a modest decrease in frequency and duration of attacks, although further larger trials are needed.[152] Botulinum toxin-A has also been studied.[153] Because of side effects, cost, and administration difficulties, these agents are primarily being studied in the most severe cases of secondary RP with digital ulcers or other systemic complications associated with connective tissue diseases. If benefit is proved, however, it will shed light on the pathogenesis of the disorder, and perhaps lead to therapies appropriate for the larger population with RP.

Statins may have promise in severe cases resulting in digital ulcers secondary to systemic sclerosis (SSc). Pleiotropic effects of atorvastatin 40 mg/day on endothelial function compared with placebo were investigated in 84 SSc patients who fulfilled the American College of Rheumatology criteria for classification of SSc with secondary RP despite ongoing vasodilator therapy. The study found a significant decrease in both new and the total number of digital ulcers in the atorvastatin group compared with placebo.[154]

The renin–angiotensin system mediators act as vasodilators and have been investigated in several small studies. ACE inhibitors and angiotensin receptor blockers, however, have yielded conflicting results with respect to beneficial effects in patients with RP.[155–158] Small beneficial effects have been realized, specifically with captopril 25 mg 3 times a day and losartan 12.5 to 25 mg/day; however, no benefit has been found with enalapril 20 mg once daily.[155] Fluoxetine, a selective serotonin reuptake inhibitor, was shown in one study to reduce the symptoms of RP.[159] It is hypothesized to exert its effect by depleting platelet serotonin, rendering the platelet unable to release a significant amount of the vasoconstrictive serotonin during activation and aggregation.

Alternative therapies, such as Ginkgo biloba and L-arginine, have also been studied in small trials with positive results; however, larger trials are needed to confirm the findings before these therapies can be recommended.[160–162]

All patients with RP should be counseled regarding cold avoidance and other protective measures. A CCB, extended-release nifedipine if tolerated, should be initiated if conservative measures are ineffective and titrated to the highest tolerated dose and symptom resolution. Combination therapies have not been investigated, but another agent, such as an α_1-adrenergic antagonist, may be considered in addition to the CCB if symptom resolution is not satisfactory and side effects permit.

NOCTURNAL LEG MUSCLE CRAMPS

Nocturnal leg muscle cramps are idiopathic, involuntary contractions occurring at rest that cause a visible and palpable knot in the affected muscle. This type of muscle cramp usually afflicts middle-aged to elderly persons and is a distressing and painful condition. Its cause is unknown. The two primary hypotheses that attempt to explain the pathophysiology propose neurologic impairments. One involves a central nervous system impairment of γ-aminobutyric acid,[163] and the other, an impaired peripheral response to muscle lengthening.[164] Although the incidence of nocturnal cramps is unknown, some data indicate it is very common. In a survey of veterans (95% men averaging 60 years of age), 56% complained of leg cramps, with 12% having cramping nearly every night[165]; 36% of these veterans were also attempting some type of drug treatment for their symptoms. A survey of the general population revealed that the prevalence of nocturnal leg cramps was 37% in people older than 50 years of age, and increased to 54% in people older than 80 years of age. The prevalence in men and women is equal.[166] Nocturnal leg cramps are associated with lower extremity atherosclerosis, CAD, and peripheral neurologic deficits.[166,167]

Clinical Presentation

CASE 10-3

QUESTION 1: H.C., a 62-year-old woman, complains of cramps in her left calf that began last night around 10 PM. The cramps occurred several times throughout the night and has resolved slowly this morning. These nighttime cramping episodes occur frequently, are very painful, and cause her calf muscle to become “knotted,” but is not associated with walking. She denies any trauma, fever, or chills, has no other medical problems, and takes no medications. Her physical examination, extended chemistry panel, and thyroid function tests are unremarkable, and her vital signs are stable. H.C. works at an elementary school and walks up and down stairs throughout the day. Her physician associates the pain with nocturnal leg cramps. What characteristics differentiate H.C.’s nocturnal leg cramps from other pain syndromes?

Benign nocturnal leg cramps usually occur in the early hours of sleeping; they are asymmetric and primarily affect the calf muscle and small muscles of the foot. These cramps are not associated with exercise, electrolyte or laboratory abnormalities, or medications, although cramping requiring therapy was more likely in the first year of patients being prescribed long-acting β-agonists, thiazide, and potassium-sparing diuretics.[168]

For diagnosis and treatment of nocturnal cramps, other causes of muscle cramping, including drug-induced cramps, must be excluded (Table 10-8). The onset of cramps at rest is characteristic of ordinary leg cramps and is the primary symptom used for diagnosis. Clinical signs of sodium depletion, hyperthyroidism and hypothyroidism, tetany, and lower motor neuron disease should be evaluated. Laboratory measurements such as standard electrolytes and thyroid function tests can help rule out some of these other conditions.

Table 10-8

Other Causes of Muscle Cramps[169–171]

Drug-Induced Cramps	Biochemical Causes	Other
Alcohol	Dehydration	Contractures
Antipsychotics (dystonia)	Hemodialysis	Diabetes
β-Agonists (e.g., albuterol, terbutaline, salbutamol)	Hypocalcemia	Lower motor neuron disease
Cimetidine	Hypokalemia	Peripheral vascular disease
Clofibrate	Hypomagnesemia	Tetany
Diuretics	Hyponatremia	Thyroid disease
Lithium	Uremia	
Narcotic analgesics		
Nicotinic acid		
Nifedipine		
Penicillamine		
Statins		
Steroids		

Treatment

THERAPEUTIC OBJECTIVES AND NONPHARMACOLOGIC INTERVENTIONS

CASE 10-3, QUESTION 2: What are the therapeutic objectives in treating H.C.? What nonpharmacologic recommendations can be made?

The primary treatment goal is to prevent this uncomfortable condition. Given the limited evidence and potential side effects with drug therapy, nonpharmacologic therapy is the preferred initial therapy. Patients are commonly advised to stretch out the afflicted muscle or perform dorsiflexion of the feet throughout the day and before bedtime.[170] Patients are also warned to avoid plantar flexion while sleeping by hanging the feet over the edge of the bed when sleeping on the stomach. Once a cramp occurs, the goal is to relieve the cramp as quickly as possible. Acute therapy consists of dorsiflexion (grasping the toes and pulling them upward in the opposite direction of the cramp). This can be accomplished with the hands, by walking, or by leaning toward a wall while standing 2 feet away from it, maintaining the feet flat on the floor.[172]

PHARMACOTHERAPY

CASE 10-3, QUESTION 3: H.C. adopted the recommended stretching practices, and reduced plantar flexion during sleep. She returns 3 months later, and reports a minor decrease in the attack frequency, but not severity. Her sleep is affected 2 to 3 nights/week, and she feels it is affecting her performance as a teacher. She remembers her aunt taking a "pill" for her leg cramps. Are there any medications that may help relieve her symptoms?

A variety of medications have been reported to help treat nocturnal leg cramps, but all have limited, very limited, and inconclusive evidence. Vitamin B_{12}, vitamin E, diphenhydramine, gabapentin, diltiazem, and verapamil have limited effectiveness data, mostly via small single trials or case series. Quinine historically had been the most frequently prescribed medication for nocturnal leg cramps. The FDA, however, has clearly stated quinine should not be used for nocturnal leg cramps because of an unfavorable risk–benefit ratio.[173]

Quinine has been used to treat nocturnal leg cramps since the 1940s, when four patients having leg cramps experienced marked improvement in symptoms after being treated with quinine.[174] Despite its use, significant controversy exists about its benefit. Only a few small controlled trials have been conducted, with mixed conclusions. A meta-analysis was published in 1998 that included both published and unpublished data addressing the efficacy of quinine in the treatment of leg cramps.[175] Pooled data from 659 patients indicated that quinine, at 200 to 325 mg/day, reduced the severity and average number of cramps experienced in a 4-week period from 17.1 to 13.5. Of note, a recent study that randomly assigned patients to quinine cessation reported no effect on nocturnal leg cramp frequency (e.g., no worsening of symptoms).[176]

Cinchonism, a syndrome that includes nausea, vomiting, blurred vision, tinnitus, and deafness, is a dose-related side effect of quinine.[169] Tinnitus alone occurs in up to 3% of patients.[177] With overdose, central nervous system manifestations, such as headache, confusion, and delirium, can occur. Self-limiting rashes

---

that resolve with drug discontinuation have been described.[169] The unpredictable and life-threatening side effect of thrombocytopenia was the impetus for the FDA to ban the over-the-counter status of this preparation. Thrombocytopenia has been estimated to occur in up to 1 of 1,000 patients taking quinine.[173] Care should also be taken with the use of quinine because its clearance is decreased in the elderly,[178] and several drugs decrease its clearance, such as cimetidine, verapamil, amiodarone, and alkalinizing agents.[179] Quinine can also produce toxic levels of digoxin, phenobarbital, and carbamazepine[180] and is contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency.

OTHER THERAPIES

CASE 10-3, QUESTION 4: Are there other treatment options for H.C.?

Electrolyte replacement (e.g., sodium, potassium, calcium, magnesium) may be indicated if specific deficiencies are noted or if the onset of cramping is associated with a recent initiation or dosage increase of diuretic therapy. Prophylactic use of other pharmacologic agents has been attempted, but their use is mostly anecdotal. Diphenhydramine, riboflavin, carbamazepine, methocarbamol, and phenytoin have been used empirically,[169] but no data support their use in nocturnal leg cramps. Vitamin E has been recommended, but one controlled study with 800 international units/day of vitamin E showed no benefit.[180] Verapamil has been shown in an open-label trial of eight elderly patients to relieve quinine-resistant cramps. A dose of 120 mg of verapamil at bedtime was used, and relief was seen after 6 days of treatment.[180] Similar results were reported from a similar small study using diltiazem.[181] A small study found benefit associated with vitamin B complex administration for nocturnal leg cramps, but no quantification of a decrease in the number of cramps was provided.[182] Two small crossover studies suggested that chronic magnesium administration is not effective for the treatment of nocturnal leg cramps.[183,184]

Although nocturnal leg cramps are relatively benign, they do cause considerable discomfort. Nonpharmacologic measures should be maximized before drug therapy is contemplated. If drug therapy is warranted, quinine can be tried, but the potential for side effects, especially in the elderly population, is very real. Careful patient selection, patient education, and vigilant monitoring for side effects should all be used to minimize the occurrence and progression of adverse effects from quinine.

Thrombosis

Nancy L. Shapiro and Erika L. Hellenbart

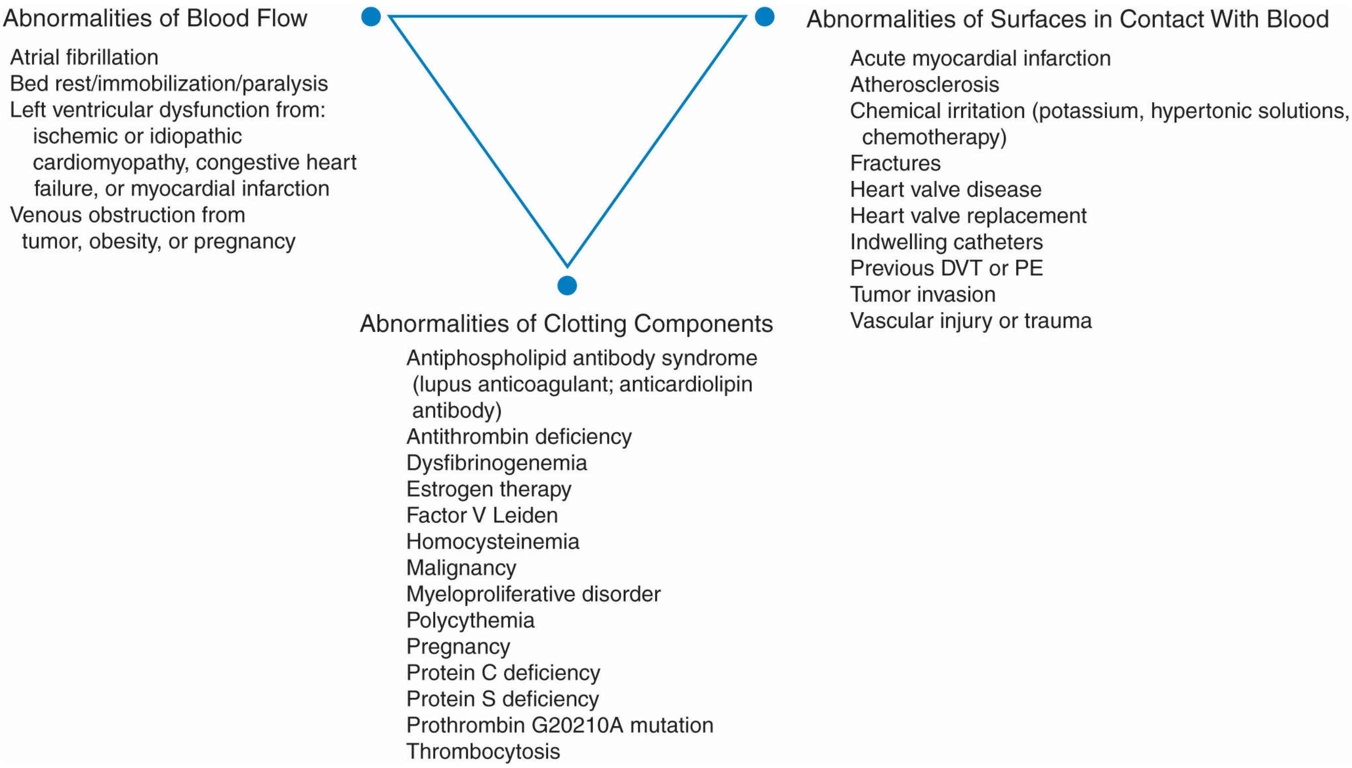
CORE PRINCIPLES

		CHAPTER CASES
1	Venous thromboembolism (VTE), including deep vein thrombosis (DVT) and pulmonary embolism (PE), is caused by numerous additive risk factors, with diagnosis based on clinical findings and objective criteria.	**Case 11-1 (Questions 1–3), Case 11-5 (Question 1)**
2	VTE treatment includes parenteral anticoagulants (low-molecular-weight heparins or fondaparinux) bridging to a therapeutic international normalized ratio (INR) with warfarin, parenteral anticoagulants given before transitioning to dabigatran or edoxaban, or as monotherapy with rivaroxaban or apixaban.	**Case 11-1 (Questions 4–6, 9), Case 11-5 (Questions 2, 3)**
3	Unfractionated heparin is monitored with the activated partial thromboplastin time (aPTT) test; dosing adjustments are used to maintain the aPTT in therapeutic range, as well as monitoring for adverse effects, including thrombocytopenia and bleeding.	**Case 11-1 (Questions 7, 8, 10–12), Case 11-2 (Question 1)**
4	Outpatient treatment of VTE is preferred over hospitalization for patients with DVT and low-risk PE and home circumstances that are adequate.	**Case 11-3 (Questions 1, 2)**
5	Anticoagulation prophylaxis should be used in hospitalized patients at risk of VTE.	**Case 11-4 (Question 1)**
6	Warfarin therapy is dosed and monitored according to therapeutic response as measured by the INR. Monitoring for adverse effects including hemorrhage is also essential for all anticoagulants.	**Case 11-5 (Questions 4–6), Case 11-6 (Questions 5, 6), Case 11-7 (Question 1)**
7	Warfarin therapy is influenced by multiple factors, and patients on warfarin require extensive and ongoing education to maintain safe and effective anticoagulation.	**Case 11-6 (Questions 1–4), Case 11-8 (Question 1), Case 11-13 (Question 1), Case 11-14 (Questions 1, 2)**
8	Warfarin and the direct oral anticoagulants (DOACs) are used for stroke prevention in nonvalvular atrial fibrillation. Warfarin is the only long-term oral option for stroke prevention for thrombosis prevention in patients with artificial heart valve replacement.	**Case 11-9 (Questions 1–3), Case 11-10 (Question 1), Case 11-11 (Question 1)**
9	Pharmacists can play an important role in the management of anticoagulant therapy for invasive procedures.	**Cases 11-12 (Question 1)**

10 Although the DOACs do not need monitoring to measure their efficacy, monitoring of baseline renal function and complete blood cell counts are necessary to ensure appropriateness of dosing and to minimize risk of anticoagulation-related bleeding complications.	**Case 11-3 (Question 1), Case 11-5 (Questions 2, 6)**

GENERAL PRINCIPLES

Thrombosis is the process involved in the formation of a fibrin blood clot. Platelets and a series of coagulant proteins (clotting factors) contribute to clot formation. An embolus is a small part of a clot that breaks off and is carried by blood flow to another part of the vascular system. Damage is caused when the embolus becomes trapped in a small vessel, causing occlusion and leading to ischemia or infarction of the surrounding tissue. Normal clot formation maintains the integrity of the vasculature in response to injury, but pathologic clotting can occur in many clinical settings. Abnormal thrombotic events include venous thromboembolism (deep venous thrombosis [DVT] and its primary complication, pulmonary embolism [PE]), as well as stroke and other systemic manifestations of embolization of clots that form within the heart. Anticoagulant drug therapy is aimed at preventing pathologic clot formation in patients at risk and at preventing clot extension and/or embolization in patients who have experienced thrombosis. This chapter emphasizes arterial and venous thromboembolic disease and the use of the parenteral anticoagulants (unfractionated heparin, low-molecular-weight heparins, indirect factor Xa inhibitors, and injectable direct thrombin inhibitors) and oral agents (vitamin K antagonists, and direct oral anticoagulants [DOACs], which include the oral direct thrombin inhibitors, and the oral direct factor Xa inhibitors). Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Artery Disease; Chapter 13, Acute Coronary Syndrome, and Chapter 61, Ischemic and Hemorrhagic Stroke, provide more in-depth discussions of thrombolytic agents and antiplatelet therapy.



Abnormalities of Blood Flow
Atrial fibrillation
Bed rest/immobilization/paralysis
Left ventricular dysfunction from:
ischemic or idiopathic cardiomyopathy, congestive heart failure, or myocardial infarction
Venous obstruction from tumor, obesity, or pregnancy
Abnormalities of Surfaces in Contact With Blood
Acute myocardial infarction
Atherosclerosis
Chemical irritation (potassium, hypertonic solutions, chemotherapy)
Fractures
Heart valve disease
Heart valve replacement
Indwelling catheters
Previous DVT or PE
Tumor invasion
Vascular injury or trauma
Abnormalities of Clotting Components
Antiphospholipid antibody syndrome (lupus anticoagulant; anticardiolipin antibody)
Antithrombin deficiency
Dysfibrinogenemia
Estrogen therapy
Factor V Leiden
Homocysteinemia
Malignancy
Myeloproliferative disorder
Polycythemia
Pregnancy
Protein C deficiency
Protein S deficiency
Prothrombin G20210A mutation
Thrombocytosis

Figure 11-1 Risk factors for thromboembolism.

Etiology of Thromboembolism

Three primary factors influence the formation of pathologic clots and are described in a model referred to as Virchow's triad (Fig. 11-1).[1] Abnormalities of blood flow that cause venous stasis can result in DVT, which can progress to PE if embolization occurs. Intracardiac stasis of blood can also result in clot formation within the heart chambers, and embolization of intracardiac thrombi may lead to stroke or other systemic manifestations. Abnormalities of blood vessel walls, such as those that occur in injury or trauma to the vasculature, are a second source of thrombus formation. The presence of foreign material within the vasculature, including artificial heart valves and central venous catheters, is also thrombogenic and, like vascular injury, represents the presence of an abnormal surface in contact with blood. Finally, hypercoagulability resulting from alterations in the availability or the integrity of blood-clotting components or naturally occurring anticoagulants also represents a significant risk factor for thromboembolic disease.[2]

Clot Formation

The intact endothelial lining of blood vessels normally repels platelets and inhibits clot formation through secretion of numerous inhibitory substances. Damage to the endothelium leads to exposure of circulating blood to subendothelial substances, and this results in formation of a fibrin clot.[2]

PLATELET ADHESION, ACTIVATION, AND AGGREGATION

Endothelial damage leads to exposure of blood to subendothelial collagen and phospholipids, resulting in platelet adhesion to the surface. Von Willebrand factor serves as the binding ligand for platelet adhesion, via the glycoprotein I (GPI) receptor on the platelet surface. Adhered platelets become activated and release numerous compounds, including adenosine diphosphate and thromboxane A2, which stimulate platelet aggregation. Fibrinogen serves as the binding ligand for platelet aggregation, via the GPIIb/IIIa receptor on the platelet surface.[2]

CLOTTING CASCADE

Transformation of the relatively unstable platelet plug (i.e., the aggregated platelets) to a stable fibrin clot occurs as a result of an imbalance between other procoagulant and anticoagulant factors. In addition to stimulating the platelet response, endothelial damage results in activation of the extrinsic pathway of the clotting cascade by the release of thromboplastin (tissue factor) (Fig. 11-2). Tissue factor converts factor VII to factor VIIa, which mediates the activation of factor X. The intrinsic pathway of the clotting cascade is activated by exposure of factor XII to subendothelial components exposed during vessel injury. The intrinsic pathway mediates factor X activation via a chain of events initiated by factor XI. The distinction between these pathways is primarily an in vitro phenomenon; in vivo, the two pathways are activated simultaneously.

Once stimulated, both the extrinsic and intrinsic pathways activate the common pathway of the clotting cascade via factor X. Activated forms of factors V and VIII serve independently to accelerate this process. The final steps include conversion of factor II (prothrombin) to factor IIa (thrombin), with eventual formation of a stable fibrin clot.

Naturally occurring inhibitors of clotting factors play a role in localizing fibrin formation to the sites of injury and in maintaining the fluidity of circulating blood. Table 11-1 outlines these clotting inhibitors and their primary actions. In addition, the fibrinolytic system is involved in degradation of fibrin clots. The actions of both clotting inhibitors and the fibrinolytic system prevent excessive coagulation. Thus, the process of clot formation is dynamic and involves various factors that can stimulate, inhibit, and dissolve a fibrin clot.

PATHOLOGIC THROMBI

Pathologic thrombi are sometimes classified according to location and composition. Arterial thrombi are composed primarily of platelets, although they also contain fibrin and occasional leukocytes. Arterial thrombi generally occur in areas of rapid blood flow (i.e., arteries) and are typically initiated by spontaneous or mechanical rupture of atherosclerotic plaques followed by aggregation of platelets (see Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease; and Chapter 13, Acute Coronary Syndrome). Venous thrombi are found primarily in the venous circulation and are composed almost entirely of fibrin and erythrocytes. Venous thrombi have a small platelet head and generally form in response to either venous stasis or vascular injury after surgery or trauma. The areas of stasis prevent dilution of activated coagulation factors by normal blood flow.

The selection of an antithrombotic agent is influenced by the type of thrombus to be treated. The anticoagulants heparin, low-molecular-weight heparins (LMWHs), indirect and direct factor Xa inhibitors, direct thrombin inhibitors, and warfarin are used in the treatment and prevention of both arterial and venous thrombi. Drugs that alter platelet function (e.g., aspirin, clopidogrel), alone and/or in combination with anticoagulants, are primarily used in the prevention of arterial thrombi. Fibrinolytic agents are used for rapid dissolution of thromboemboli, most notably during myocardial infarction (MI).

Table 11-1

Inhibitors of Clotting Mechanisms

Inhibitor	Target
Antithrombin	Inhibits factors IIa, IXa, and Xa
Protein S	Cofactor for activation of protein C
Protein C	Inactivates factors Va and VIIIa
Tissue factor pathway inhibitor	Inhibits activity of factor VIIa
Plasminogen	Converted to plasmin via tissue plasminogen activator
Plasmin	Lyses fibrin into fibrin degradation products

Pharmacology of Antithrombotic Agents

HEPARIN

Heparin is a rapid-acting anticoagulant that is administered parenterally. Standard heparin (unfractionated heparin [UFH]) is a heterogeneous mixture of glycosaminoglycans of varying molecular weights obtained from bovine lung or porcine intestinal mucosa (Table 11-2). The action of heparin is facilitated by its binding to the naturally circulating anticoagulant antithrombin (AT), a serine protease also referred to as heparin cofactor. Binding of heparin to AT accelerates the anticoagulant effect of AT. The heparin–AT complex attaches to and irreversibly inactivates factor IIa (thrombin) and factor Xa, as well as activated factors IX, XI, and XII.[3] Approximately one-third of the molecules present in UFH bind to AT and provide the anticoagulant properties of heparin. The remaining two-thirds of the heparin molecules bind to plasma proteins and to endothelial cells. In addition to its anticoagulant effects, heparin inhibits platelet function and increases vascular permeability; these properties contribute to the hemorrhagic effects of heparin.

In cases of acute DVT or PE, the clotting cascade has been activated, generating abnormal quantities of thrombin and fibrin. In these situations, thrombin must be inactivated directly, a process that may require relatively large doses of heparin. However, when the clotting cascade is in a normal balance, it is possible to indirectly inactivate thrombin with smaller heparin doses by complexing factor Xa. Because of the amplification effect of the clotting cascade, inactivation of relatively small amounts of factor Xa indirectly prevents the production of large quantities of thrombin. This phenomenon is the basis for low-dose heparin prophylaxis after surgery or in cases of prolonged bed rest or immobilization.

Heparin may be administered intravenously (IV) by continuous infusion, or subcutaneously (SC), although its bioavailability is significantly reduced by SC administration. Intramuscular administration of heparin (as well as intramuscular administration of other drugs in patients who are anticoagulated) should be avoided because of the potential for hematoma formation.

After IV administration, the anticoagulant effect of heparin is noted immediately.

During active thromboembolism, the high concentration of clotting factors necessitates a higher concentration of heparin to neutralize them. This increased dosing requirement may also be related to continuing thrombin formation on the surface of the thrombus. Once endothelialization (localization and incorporation of the clot into the vascular endothelium) of the clot begins and the concentration of clotting factors decreases, dosing requirements typically decrease. Considerable variability in dosing requirements among patients necessitates routine therapeutic monitoring to maintain an appropriate intensity of anticoagulation with heparin. The primary laboratory test for monitoring therapeutic heparinization is the activated partial thromboplastin time (aPTT) (see Tests Used to Monitor Antithrombotic Therapy section).

Table 11-2

Comparison of Unfractionated Heparin, Low-Molecular-Weight Heparins, and Fondaparinux

Property	UFH	LMWH	Fondaparinux
Molecular weight range[a]	3,000–30,000	1,000–10,000	1,728
Average molecular weight[a]	12,000–15,000	4,000–5,000	1,728
Anti-Xa: anti-IIa activity	1:1	2:1–4:1	>100:1
aPTT monitoring required	Yes	No	No
Inactivation by platelet factor 4	Yes	No	No
Capable of inactivation of platelet-bound factor Xa	No	Yes	Yes
Inhibition of platelet function	++++	++	No
Increases vascular permeability	Yes	No	No
Protein binding	++++	+	No
Endothelial cell binding	+++	+	No
Dose-dependent clearance	Yes	No	No
Primary route of elimination	Saturable binding processes Renal	Renal	Renal
Elimination half-life	30–150 minutes	2–6 hours	17 hours

[a] Measured in daltons.

LMWH, low-molecular-weight heparin; UFH, unfractionated heparin.

Source: Garcia DA et al. Parenteral anticoagulants: antithrombotic therapy and prevention of thrombosis, 9th ed: American College of Chest Physicians evidence-based clinical practice guidelines. Chest. 2012;141:e24S–e43S.

The plasma half-life of heparin varies from 30 to 150 minutes, but the half-life increases with increasing doses. Heparin is cleared by extensive binding to plasma proteins and endothelial cells, saturable processes that explain both its nonlinear kinetics and the variability in dosing requirements among patients. Additional clearance occurs by transfer to the reticuloendothelial system, with ultimate elimination controlled by the kidneys.

LOW-MOLECULAR-WEIGHT HEPARINS

By using chemical or enzymatic depolymerization techniques, UFH can be separated into fragments based on molecular weight.[3] Several LMWH molecules have been isolated and commercially marketed as anticoagulants. The LMWH products available in the United States are dalteparin and enoxaparin, and tinzaparin is available in the non-US market (Table 11-3). These products have replaced the use of UFH in many clinical situations. These compounds differ substantially from UFH with respect to molecular weight, antithrombotic and pharmacokinetic properties, adverse effect profiles, and monitoring requirements (Table 11-2).

To inactivate factor Xa, only the AT component of the heparin–AT complex is required to bind to factor Xa. Both the longer, high-molecular-weight fragments of UFH and the shorter, low-molecular-weight fragments of LMWHs are capable of inactivating factor Xa. However, to inactivate factor IIa (thrombin), both the heparin component and the AT component of the heparin–AT complex are required to bind to factor IIa. This binding requires heparin molecules of at least 18 saccharide units in length, which are less prevalent in LMWHs. Therefore, the anti-Xa properties of LMWHs are more significant than their anti-IIa properties. The resultant antithrombotic effect does not prolong the aPTT, meaning that these compounds do not require laboratory monitoring in most clinical circumstances to ensure a therapeutic effect.

Additional advantages of LMWHs over UFH are explained by their reduced binding affinity for plasma proteins and endothelial cells. These compounds display improved bioavailability after SC injection, a predictable dose response, and a longer pharmacodynamic effect compared with UFH. In general, these compounds are administered subcutaneously every 12 to 24 hours at fixed doses. The LMWH products have been studied in the prevention and treatment of thromboembolic disease. They differ significantly in their molecular weight distributions, methods of preparation, and the ratio of anti-Xa: anti-IIa activities, as well as in their pharmacokinetic and pharmacodynamic characteristics (Table 11-2).

FACTOR Xa INHIBITORS

Fondaparinux is a selective indirect factor Xa inhibitor that is indicated for the prevention of venous thrombosis associated with orthopedic surgery and abdominal surgery, and for the treatment of deep vein thrombosis and pulmonary embolism.[3,4] It is a synthetic derivative of the five-residue saccharide sequence found in both UFH and LMWH that binds to AT to inactivate factor Xa with no direct impact on factor IIa. This agent has a long elimination half-life, allowing for once-daily SC administration at a fixed dose without the need for routine coagulation monitoring

(Table 11-2).

Table 11-3

Low-Molecular-Weight Heparin Products

Generic Name	Brand Name	Average Molecular Weight (Range)[a]	Anti-Xa: Anti-IIa Activity
Dalteparin	Fragmin	5,000 (2,000–9,000)	2.0:1
Enoxaparin	Lovenox	4,500 (3,000–8,000)	2.7:1
Tinzaparin[b]	Innohep	4,500 (3,000–6,000)	1.9:1

[a] Measured in daltons.

[b] Not available in the United States.

Table 11-4

Comparative Pharmacokinetic and Pharmacodynamics Properties of the DOACs

Agent	Dabigatran	Rivaroxaban	Apixaban	Edoxaban	Betrixaban
Mechanism	Direct thrombin inhibitor	Direct factor Xa inhibitor	Direct factor Xa inhibitor	Direct factor Xa inhibitor	Direct factor Xa inhibitor
Bioavailability (%)	6	60–80	66	62	34
Tmax (hours)	2–3	2–4	1–3	1–2	3–4
Renal excretion of unchanged drug (%)	80	33	25	50	11
Half-life (hours)	14–17	5–9 11–13 (elderly)	8–15	10–15	19–27
Dialyzable	Yes	No	No	No	Unknown
CYP enzyme substrate	No	CYP 3A4 CYP 2J2	CYP 3A4	Minimal	Minimal
P-gp substrate	Yes	Yes	Yes	Yes	Yes

Direct factor Xa inhibitors include the oral agents apixaban, edoxaban, and rivaroxaban. These agents are currently approved by the US Food and Drug Administration (FDA) for stroke prevention in nonvalvular atrial fibrillation, and prevention and treatment of venous thromboembolism (VTE), with other indications being investigated. Betrixaban is the newest agent to receive FDA approval, and is indicated for prophylaxis of VTE in adult patients hospitalized for an acute medical illness. These agents have a short onset of action and elimination half-life, are given at fixed doses, and do not require routine monitoring or dose adjustments, which offers significant benefits to warfarin therapy as chronic therapy (Table 11-4). Each have varying dependence on renal function for elimination but all require dose adjustments in patients with renal dysfunction. However, low body weight or advanced age necessitates a dose reduction for apixaban (Table 11-5). All are substrates of P-glycoprotein (P-gp); thus, concomitant use of inducers and inhibitors of P-gp can, respectively, decrease and increase its serum concentration. Additionally, rivaroxaban and apixaban are both substrates of cytochrome P450 enzyme 3A4 (CYP 3A4) and require dose adjustments when used concomitantly with certain CYP 3A4 inhibitors or inducers (Tables 11-5 and 11-6).

DIRECT THROMBIN INHIBITORS

Argatroban, lepirudin, and bivalirudin are injectable direct thrombin inhibitors that are used as alternative anticoagulants in patients with heparin-induced thrombocytopenia. Lepirudin, however, is no longer readily available in most countries, including the United States[5] (Table 11-7). Direct thrombin inhibitors bind to specific sites on the thrombin molecule to inhibit its activity, without acting through a cofactor like antithrombin. These agents are administered by continuous infusion and require aPTT monitoring for appropriate dosing adjustments. Bivalirudin is also used in patients with acute coronary syndrome, including those undergoing percutaneous coronary intervention (see Chapter 13, Acute Coronary Syndrome).

Dabigatran is an oral direct thrombin inhibitor, approved for stroke prevention in patients with nonvalvular atrial fibrillation, the treatment of VTE, and the extended treatment of VTE.[6] Similar to the direct factor Xa inhibitors, dabigatran is given at a fixed dose without the need for routine coagulation monitoring or dosing adjustments.[6] It has a short onset of action and elimination half-life in patients with normal renal function, which reduces the need for bridging therapy with LMWH as is necessary during warfarin initiation or interruption (Table 11-4). Due to its low bioavailability, dabigatran is administered as a prodrug, dabigatran etexilate, in a capsule form that contains small micropellets that coat dabigatran with tartaric acid, creating an acidic microenvironment. It is then rapidly converted to the active compound by hydrolysis and then eliminated renally. When it is not supplied or stored in the original packaging, capsule exposure to humidity leads to degradation of dabigatran etexilate via hydrolysis. Shelf life of dabigatran is 4 months if stored and sealed in the original bottle and desiccant-containing cap. Blister packs are available for unit-dose administration. Elimination of dabigatran is highly dependent on renal function so dosing adjustments are required in these patients (Table 11-5). Dabigatran is a substrate of P-gp; thus, concomitant use of inducers and inhibitors of P-gp can, respectively, decrease and increase its serum concentrations. However, because dabigatran is not metabolized by cytochrome P-450 (CYP) enzymes, it is not susceptible to CYP-mediated drug interactions (Table 11-6). Collectively, the oral direct thrombin inhibitors and the oral direct factor Xa inhibitors are referred to as direct oral anticoagulants (DOACs). The DOACs represent additional options for patient care and many new opportunities for pharmacist involvement in drug selection, patient education, and long-term therapeutic management.

WARFARIN

Warfarin is an oral anticoagulant with a delayed onset of effect that acts as a vitamin K antagonist (VKA). Vitamin K is essential for the conversion (carboxylation) of precursors to clotting factors II, VII, IX, and X into inactive clotting factors and for the synthesis of the naturally occurring anticoagulants, protein C and protein S. During factor conversion, vitamin K is oxidized to inactive vitamin K epoxide (Fig. 11-3). In the nonanticoagulated patient, vitamin K epoxide is in reversible equilibrium with vitamin K, but this equilibrium is disrupted in patients taking oral vitamin K antagonists. Warfarin interferes with the hepatic recycling of vitamin K by inhibiting vitamin K epoxide reductase (VKOR), the enzyme that converts vitamin K epoxide to vitamin K.[6] The accumulation of vitamin K epoxide reduces the effective concentration of vitamin K and reduces the synthesis of coagulation factors. Concentrations of clotting factors II, VII, IX, and X are diminished gradually at rates commensurate with their elimination half-lives (Table 11-8). Thus, the onset of the anticoagulant effect of warfarin is delayed. It takes approximately 5 to 7 days to reach a steady state of anticoagulation after warfarin therapy is initiated or after dosing changes. Protein C and its cofactor protein S are also vitamin K dependent, and these proteins are depleted by warfarin at rates dependent on their elimination half-lives.

Table 11-5

Approved Dosing of the DOACs for AF and VTE

	Atrial Fibrillation[a]	VTE Treatment
Dabigatran	CrCl > 30 mL/minute: 150 mg BID CrCl 30–50 mL/minute on dronedarone or ketoconazole: decrease to 75 mg BID CrCl 15–30 mL/minute: 75 mg BID or avoid if on P-gp inhibitor CrCl < 15 mL/minute or on dialysis: dosing recommendations cannot be provided	CrCl > 30 mL/minute: LMWH or UFH × 5–10 days then dabigatran 150 mg BID CrCl < 50 mL/minute and on P-gp inhibitor: avoid coadministration CrCl ≤ 30 mL/minute or on dialysis: dosing recommendations cannot be provided Extended treatment to prevent VTE recurrence (CrCl > 30 mL/minute): 150 mg BID
Rivaroxaban	Dosed with evening meal: CrCl > 50 mL/minute: 20 mg daily CrCl 15–50 mL/minute: 15 mg	CrCl ≥ 30 mL/minute: 15 mg BID × 21 days then 20 mg daily CrCl < 30 mL/minute: avoid Extended treatment to prevent VTE recurrence: 20 mg

	daily CrCl < 15 mL/minute: avoid	daily
Apixaban	Most patients: 5 mg BID Any two of the following: 2.5mg BID: SCr ≥ 1.5mg/dL Age ≥ 80 years Weight ≤ 60 kg	10 mg BID × 7 days then 5 mg BID No dose adjustment recommended for renal function[b] Extended treatment to prevent VTE recurrence: 2.5 mg BID Strong dual inhibitors of CYP3A4 and p-glycoprotein (P-gp): reduce dose by 50% if taking 5 mg or 10 mg ■ If already taking 2.5 mg BID: avoid use Dual P-gp inducers and strong CYP3A4 inducers: avoid concomitant use
Edoxaban	CrCl > 95 mL/minute: do not use CrCl > 50–95 mL/minute: 60 mg daily CrCl 15–50 mL/minute: 30 mg daily CrCl < 15 mL/minute: use is not recommended	CrCl > 50 mL/minute: LMWH or UFH × 5–10 days then edoxaban 60 mg daily CrCl 15–50 mL/minute: 30 mg daily CrCl < 15 mL/minute: use is not recommended Pts ≤ 60 kg or on P-gp inhibitors: 30 mg daily

[a] DOACs are only indicated for nonvalvular AF.

[b] Patients with CrCl < 25 mL/minute excluded from clinical trials for apixaban.

BID, twice daily.

Table 11-6

Drug Interactions with the DOACs

Drug	Recommendation
Dabigatran	P-gp inhibitors: Reduced dose recommended with CrCl 30–50 mL/min and ketoconazole or dronedarone CrCl 15–30 mL/minute: AVOID concomitant use
	P-gp inducers: AVOID concomitant use with rifampin
Rivaroxaban	P-gp inhibitors and strong CYP3A4 inhibitors: Avoid concomitant use (e.g., ketoconazole, itraconazole, ritonavir, indinivir, conivaptan)
	P-gp inducers and strong CYP3A4 inducers: Avoid concomitant use (e.g., carbamazepine, phenytoin, rifampin, St. John’s wort)
Apixaban	P-gp inhibitors and strong CYP3A4 inhibitors: Reduced dose recommended, or avoid concomitant use if currently on lowest dose (2.5mg)
	P-gp inducers and strong CYP3A4 inducers: Avoid concomitant use (e.g., carbamazepine, phenytoin, rifampin, St. John’s wort)
Edoxaban	P-gp inhibitors (e.g., verapamil, quinidine, azithromycin, clarithromycin, erythromycin, itraconazole, or ketoconazole) AF: No dose reduction is recommended VTE: Reduced dose recommended
	P-gp inducers: AVOID concomitant use with rifampin

Betrixaban	P-gp inhibitors (e.g., amiodarone, azithromycin, verapamil, ketoconazole, clarithromycin) Medical prophylaxis: Reduced dose recommended
	P-gp inducers: no warnings at this time

IX	21–30
X	27–48
Protein C	9
Protein S	60

Warfarin is rapidly and completely absorbed in the upper gastrointestinal (GI) tract by passive diffusion, with nearly 100% bioavailability. Peak absorption of warfarin occurs in 60 to 120 minutes. It is approximately 99% bound to serum albumin. The volume of distribution for warfarin is 12.5% of body weight. This small volume of distribution is consistent with the extensive binding of warfarin to albumin. The primary laboratory test for monitoring warfarin therapy is the prothrombin time (PT). No correlation appears to exist between PT and the dose of warfarin, the total warfarin concentration, or the free warfarin concentration for any population of treated patients, although in individual patients an increasing dose of warfarin will increase the serum concentration (free and total) and the PT.

Warfarin is administered orally as a racemic mixture containing equal parts of the enantiomers R(+)-warfarin and S(−)- warfarin. The S(−)-isomer is 2.7 to 3.8 times more potent as an anticoagulant than the R(+)-isomer, has a longer elimination half-life, and is primarily metabolized by CYP2C9. Comparatively, R(+)-warfarin is metabolized primarily by CYP1A2 and CYP3A4. Many drugs interact with warfarin by stereoselectively inhibiting the metabolism of either the R(+)-isomer or the S(−)-isomer (see Drug Interactions section).

Genetic expression of CYP2C9 influences the rate of metabolism of warfarin and thus impacts dosing requirements to meet a particular therapeutic end point.[7] Variability in genetic expression of VKORC1 (the C1 subunit on the gene that codes for VKOR) also influences dosing requirements in patients taking warfarin. Genetic testing for CYP2C9 genotype and VKORC1 haplotype can be incorporated with clinical and demographic information to predict warfarin dose requirements in individual patients, using dosing algorithms that have

---

been developed and investigated. A practical example is available online at www.warfarindosing.org. Routine pharmacogenomic testing of warfarin is not currently endorsed at this time.

Tests Used to Monitor Antithrombotic Therapy

Before the initiation of any antithrombotic therapy, an assessment of baseline hemostatic status is necessary. The clinician should obtain a baseline platelet count and hemoglobin (Hgb) and/or hematocrit (Hct), as well as evaluate the baseline integrity of the extrinsic and intrinsic coagulation pathways with PT and aPTT, the tests used to monitor warfarin and heparin, respectively. The DOACs do not require routine monitoring of laboratory tests to monitor their efficacy; however, because they have different doses based on renal function, baseline CrCl is needed with these agents.

PROTHROMBIN TIME/INTERNATIONAL NORMALIZED RATIO

The PT is prolonged by deficiencies of clotting factors II, V, VII, and X, as well as by low levels of fibrinogen and very high levels of heparin. It reflects alterations in the extrinsic and common pathways of the clotting cascade, but not in the intrinsic system.[8] The PT is measured by adding calcium and tissue thromboplastin to a sample of plasma from which platelets have been removed by centrifugation. The time to clot formation is detected by automated instruments using light scattering techniques that measure optical density. The mean normal PT, obtained by averaging a number of PT results from nonanticoagulated subjects, is approximately 12 seconds for most reagents.

The thromboplastins used in PT monitoring are extracted from various tissue sources by a number of techniques and prepared for commercial use as reagents. Unfortunately, thromboplastins are not standardized among manufacturers or among batches of reagent produced by the same manufacturer, leading to significant variability in PT results for anticoagulated patients. To standardize PT results, the World Health Organization developed a system by which all commercially available thromboplastins are compared with an international reference thromboplastin and then assigned an international sensitivity index (ISI). This value is used to mathematically convert PT to the international normalized ratio (INR) by exponentially multiplying the PT ratio to the power of the ISI of the thromboplastin being used in the laboratory to measure the test:

$$\text{INR} = (\text{PT patient} / \text{PT mean normal})^{\text{ISI}} \quad \text{(Eq. 11-1)}$$

The ISI of the international reference thromboplastin is 1.0.

The INR is the internationally recognized standard for monitoring warfarin therapy.[9] Current recommendations for intensity of oral anticoagulation therapy for accepted clinical indications are summarized in Table 11-9. Regular intensity therapy is defined as dosing warfarin to reach a goal INR of 2.5 (range, 2.0–3.0) and is appropriate for most settings that require the prevention and/or treatment of thromboembolic disease. High-intensity therapy is used in mechanical valve replacement and certain situations of thromboembolic recurrence, despite adequate anticoagulation, and is defined as dosing warfarin to reach a goal INR of 3.0 (range, 2.5–3.5).

ACTIVATED PARTIAL THROMBOPLASTIN TIME

The aPTT reflects alterations in the intrinsic pathway of the clotting cascade and is used to monitor heparin and injectable direct thrombin inhibitors.[8,9] The test is performed by adding a surface-activating agent (kaolin or micronized silica), a partial thromboplastin reagent (phospholipid; platelet substitute), and calcium to the plasma sample. Mean normal values vary among reagents, but typically fall between 24 and 36 seconds.

Like PT, the aPTT is a highly variable test based on differences among commercially available partial thromboplastin reagents. However, a system equivalent to the INR has not been developed for standardization of aPTT results. Heparinization to prolong the aPTT to 1.5 to 2.5 times the mean normal value historically was considered adequate to prevent propagation or extension of thrombus, but is no longer recommended because it is not appropriate for all reagents and testing systems. Instead, the aPTT should be calibrated for each reagent lot and coagulometer, and a reagent-specific therapeutic range in seconds should be determined that corresponds to therapeutic heparin levels of 0.3 to 0.7 international units/mL by factor Xa inhibition (anti-Xa activity).[3,9] For direct thrombin inhibitors, the same aPTT goal range is used.

Hospital-based and independent clinical laboratories that offer aPTT monitoring will report the reagent-specific therapeutic range in seconds and adjust it as new reagents are purchased and used clinically.

ANTI-FACTOR Xa ACTIVITY

Although LMWHs do not require coagulation monitoring to ensure an appropriate antithrombotic effect or to adjust dosing, certain clinical situations may require assessment of the anti-factor Xa activity of LMWHs.[3] Because these agents are eliminated renally, patients with renal failure may accumulate LMWHs, leading to an increased risk of hemorrhagic complications. Evaluation of trough anti-factor Xa activity at the end of the dosing interval can assess this accumulation of effect. LMWHs are dosed according to total body weight, but clinical trials have included only limited numbers of obese patients. Therefore, it may be appropriate to monitor anti-factor Xa activity in patients who weigh more than 150 kg. Anti-factor Xa activity may also be evaluated in patients who experience unexpected bleeding complications secondary to anticoagulation with LMWHs, and in pregnant patients in whom LMWHs are used for treatment or prevention of thrombosis.

Anti-factor Xa activity is measured using a chromogenic assay. If peak activity levels are used to assess dosing in obese and pregnant patients, they should be obtained once the patient has reached steady state, typically after three or four doses of LMWH. The anti-factor Xa level should be drawn approximately 4 hours after a SC dose of LMWH, with empiric dosing adjustments to maintain a level of roughly 0.5 to 1.0 international units/mL for therapeutic anticoagulation given every 12 hours, and slightly higher peaks up to 1.5 for therapeutic doses given every 24 hours.[3,9] However, there is little correlation between peak anti-factor Xa activity and therapeutic effect, and thus monitoring is not routinely recommended. Trough anti-factor Xa levels are expected to be less than 0.4 international units/mL at the end of the dosing interval. Like other measures of hemostasis, results vary considerably, requiring both instrument-specific and method-specific determination of therapeutic ranges.

DEEP VEIN THROMBOSIS

Clinical Presentation

SIGNS AND SYMPTOMS

CASE 11-1

QUESTION 1: J.T., a 60-year-old, overweight (92 kg, 6-foot tall) man, was admitted to the hospital 3 days ago for management of acute cellulitis of his left ankle that occurred after cutting himself with a lawn tool a week ago. He was started on intravenous antibiotics and had limited mobility in the hospital due to the pain at the wound site and is being evaluated by orthopedics for possible osteomyelitis and surgical intervention. On the third day of hospitalization, while the wound was improving, he noted progressive swelling and soreness of the left calf and around his left knee. He denied shortness of breath (SOB), cough, or chest pain. His medical history includes coronary artery disease, diabetes, and hypercholesterolemia. His medications are lisinopril 10 mg/day PO, isosorbide mononitrate 120 mg/day PO, atenolol 50 mg/day PO, aspirin 81 mg/day PO, metformin 1,000 mg PO twice daily, and atorvastatin 80 mg PO every evening. Initial laboratory values include:

Hct, 36.5%
PT, 10.8 seconds (INR, 1.0)
aPTT, 23.6 seconds
Platelet count, 255,000/µL

What signs and symptoms demonstrated by J.T. are consistent with DVT?

Table 11-9

Optimal Therapeutic Range and Duration of Anticoagulation

Indication	INR Goal	Minimum Duration
Prophylaxis of VTE (DVT, PE)	2–3	~1–4 weeks depending on patient status and risk factors
Treatment of first VTE with transient risk factors	2–3	3 months
First episode of unprovoked VTE	2–3	3 months **Consider extended treatment** if first episode of VTE is PE or proximal DVT with no bleeding risk factors
Second episode of unprovoked VTE	2–3	Long term
VTE and cancer	2–3	Indefinitely or until cancer resolved[a]
VTE prophylaxis after hip or knee arthroplasty, hip fracture surgery	2–3	Up to 35 days after surgery
Atrial fibrillation (persistent or paroxysmal)/Atrial flutter CHADS$_2$ score ≥ 1	2–3	Long term
Acute MI: high risk (large anterior MI, significant heart failure, intracardiac thrombus visible on ECHO, AF, previous VTE)	2–3	3 months
Post-UA/NSTEMI (with or without stent placement): with AF requiring dual antiplatelet therapy and warfarin therapy	2–2.5	Variable
Bileaflet mechanical valve or tilting disc valve in aortic position in sinus rhythm	2–3	Long term
Bileaflet mechanical valve or tilting disc valve in mitral position	2.5–3.5	Long term
Caged-ball or caged-disc valve	2.5–3.5	Long term

Mechanical aortic heart valves with additional risk factors (AF, previous VTE, LV dysfunction, hypercoagulable conditions)[b]	2.5–3.5	Long term
Bioprosthetic valve in aortic position[c]	N/A	Aspirin 81 mg daily alone
Bioprosthetic valve in mitral position	2–3	3 to 6 months Followed by aspirin 81 mg daily
Bioprosthetic valves with additional risk factors (AF, previous VTE, LV dysfunction, hypercoagulable conditions)	2–3	Long term

Warfarin Use in Adults: Clinical Care Guideline, University of Illinois Hospital and Health Sciences System.

[a] Low-molecular-weight heparin preferred for patients with VTE and cancer.

[b] Higher goal INR recommended by the AHA/ACC. INR 2–3 recommended by ACCP.

[c] Warfarin (goal INR 2–3) for 3 to 6 months is also recommended by the AHA/ACC.

VTE, venous thromboembolism; DVT, deep vein thrombosis; PE, pulmonary embolism; $CHADS_2$, congestive heart failure, hypertension, age ≥ 75 years, diabetes mellitus, prior stroke or transient ischemic attack; MI, myocardial infarction; ECHO, echocardiogram; AF, atrial fibrillation; EF, ejection fraction.

Patients with DVT typically present with unilateral leg swelling that often is accompanied by warmth and local tenderness or pain.[10] A tender, cordlike entity caused by venous obstruction can sometimes be palpated in the affected area. J.T. presented with the sudden onset of swelling along with soreness, but without evidence of a cord. Discoloration of the affected limb, including pallor from arterial spasm, cyanosis from venous obstruction, or a reddish color from perivascular inflammation, may also occur. The presence or absence of a positive Homans sign (pain behind the knee or calf on dorsiflexion of the foot) is rarely helpful in making the diagnosis because it is present in only about 30% of patients with DVT. Many patients (>50%) can present with asymptomatic disease, but even asymptomatic patients can have long-term complications such as recurrent DVT or post-thrombotic syndrome. Because symptoms of DVT are nonspecific, the diagnosis must be confirmed by objective testing.[10,11]

RISK FACTORS

CASE 11-1, QUESTION 2: What risk factors does J.T. exhibit that are associated with DVT?

The diagnosis of DVT depends not only on the presenting signs and symptoms but also on the presence of risk factors (Fig. 11-1). J.T. has presented with obesity and immobilization (i.e., prolonged bed rest), two important risk factors for thromboembolism, as well as an acute medical illness. It is common for more than one risk factor to be present in patients who exhibit DVT, and these factors are cumulative in their effect.[12]

DIAGNOSIS

CASE 11-1, QUESTION 3: How should the final diagnosis of DVT be made in J.T.?

After evaluation of the signs and symptoms of DVT and consideration of risk factors for the development of thrombus, a definitive diagnosis should be made. Diagnostic strategies should include an assessment of pretest clinical probability (clinical suspicion), D-dimer assay (an evaluation of the presence of fibrin degradation products, indicative of clot formation; see Chapter 2, Interpretation of Clinical Laboratory Tests), and noninvasive imaging tests.[10,11]

Despite its limitations as a single diagnostic tool, clinical assessment can improve the diagnostic accuracy of noninvasive testing. A clinical prediction rule, such as the Wells criteria, takes into account signs, symptoms, and risk factors to categorize patients as being at low, intermediate, or high probability of having DVT (Table 11-10).[13] The D-dimer test can be used in conjunction with clinical evaluation or a clinical prediction rule to help "rule out" DVT in patients with a low clinical suspicion and thus decrease the need for imaging tests in these patients.[14] If the clinical suspicion of DVT is high, diagnostic imaging is indicated, and if the imaging is negative, the D-dimer is helpful to rule out the diagnosis.[11]

The most common noninvasive test is duplex scanning, which combines B-mode imaging or color flow imaging with Doppler ultrasonography to visualize veins and thrombi while investigating flow patterns. Other noninvasive testing options include ^{125}I-fibrinogen leg scanning (injection of radiolabeled fibrinogen followed by scanning to detect areas of accumulation corresponding to thrombosis), impedance plethysmography (use of pneumatic cuffs to detect leg blood volume changes associated with thrombosis), and Doppler ultrasonography alone (use of a transducer to audibly detect venous flow changes indicative of thrombosis). Each option differs with respect to sensitivity, specificity, and cost. Venography (radiographic visualization of the involved vessels with injection of radiocontrast material), an invasive diagnostic test, is the most sensitive and specific method for diagnosis of DVT, but exposes patients to the risks associated with contrast material, and is not readily available in many hospitals.

Table 11-10

Clinical Model for Evaluating the Pretest Probability of Deep Vein Thrombosis

Clinical Characteristic	Score
Active cancer (cancer treatment within previous 6 months, or currently on palliative treatment)	1
Paralysis, paresis, or recent plaster immobilization of the lower extremities	1

Recently bedridden for ≥3 days, or major surgery within the previous 12 weeks requiring general or regional anesthesia	1
Localized tenderness along the distribution of the deep venous system	1
Entire leg swollen	1
Calf swelling at least 3 cm larger than that on the asymptomatic side (measured 10 cm below tibial tuberosity)	1
Pitting edema confined to the symptomatic leg	1
Collateral superficial veins (nonvaricose)	1
Previously documented deep vein thrombosis	1
Alternative diagnosis at least as likely as deep vein thrombosis	−2

Clinical probability of deep vein thrombosis: low, <0; moderate, 1–2; high, >3.
In patients with symptoms in both legs, the more symptomatic leg is used.

Treatment

BASELINE INFORMATION

CASE 11-1, QUESTION 4: What additional baseline data should be obtained before administering anticoagulants to J.T.?

In addition to assessing the integrity of the clotting process with platelet count, Hgb/Hct, PT, and aPTT, the patient’s baseline renal function should also be evaluated and documented because some anticoagulants are renally eliminated. Baseline values are used for comparison with the parameters that will be used in monitoring both therapeutic and adverse effects of anticoagulant therapy.

INITIATION OF THERAPY

CASE 11-1, QUESTION 5: Duplex scanning reveals clot formation in J.T.’s left calf extending to the left thigh. He does not exhibit signs of PE. What is the appropriate therapy for J.T., and how should it be initiated?

Prompt and optimal anticoagulant therapy is indicated to minimize thrombus extension and its vascular complications, as well as to prevent PE. Acute anticoagulation treatment options include injectable IV UFH initiated with a loading dose followed by a continuous infusion, adjusted-dose SC UFH, SC LMWH, or SC fondaparinux.[15] Alternatively, initial treatment with oral rivaroxaban or apixaban can be selected, without any initial parenteral anticoagulation. LMWH or UFH may be continued as monotherapy or transitioned to treatment with a VKA, dabigatran or edoxaban. Because J.T. is currently hospitalized and may need further surgical procedures, IV UFH is selected for initial treatment of his DVT.

HEPARIN

Loading Dose

CASE 11-1, QUESTION 6: J.T.'s medical resident ordered a heparin bolus dose of 5,000 international units IV, to be followed by a continuous infusion of 1,000 units/hour. Is this heparin dosing regimen appropriate?

A loading dose of heparin is required for several reasons. Based on pharmacokinetic principles, a therapeutic serum level will be achieved more quickly; thus, pharmacodynamic and therapeutic responses to help prevent progression of the clot will occur rapidly. Second, a relative resistance to anticoagulation exists during the active clotting process. Therefore, a larger initial dose generally is necessary to achieve a therapeutic effect.

Although standardized doses of heparin for initiation of therapy (i.e., 5,000 units loading dose; 1,000-units/hour maintenance dose) were used historically, this approach can result in significant

---

delays in reaching a therapeutic intensity of anticoagulation. Body weight represents the most reliable predictor of heparin dosing requirement. For patients who do not have extremes of body weight (i.e., <165 kg), the use of the actual body weight (ABW) has been recommended to calculate the initial UFH dose.[16] For patients more than 165 kg, the use of the ABW is controversial, and the use of an adjusted-dosing weight is recommended by some experts.[16,17] Options include two different "dosing weight" calculations:

$$\text{Ideal Body Weight (IBW)} + 0.3 \times (\text{ABW} - \text{IBW}) \qquad \text{(Eq. 11-2)}$$

Or

$$\text{IBW} + 0.4 \times (\text{ABW} - \text{IBW}) \qquad \text{(Eq. 11-3)}$$

Compared with standardized dosing, weight-based dosing (80 units/kg loading dose; 18 units/kg/hour initial infusion rate) increases the frequency of therapeutic aPTT at 6 hours and at 24 hours, and decreases the risk of recurrent VTE.[18–20]

Initial heparin loading doses of 60 to 100 units/kg followed by an infusion rate of 13 to 25 units/kg/hour are commonly recommended.[21] Selection of the lower or upper dosage range is guided by the severity of the patient's symptoms and his or her potential sensitivity to adverse effects. For this 92-kg patient, a midrange loading dose of 7,400 units (92 kg × 80 units/kg), followed by a continuous infusion of 1,700 units/hour (92 kg × 18 units/kg/hour), is recommended. Loading doses are typically rounded to the nearest 500 units and maintenance infusion rates to the nearest 100 units for convenience of administration.

Dose Adjustments

CASE 11-1, QUESTION 7: The orders for J.T. were rewritten by his attending physician. Based on the data shown subsequently, explain the variability in laboratory results. (At this institution, aPTT values of 60–100 seconds correspond with heparin plasma concentrations of 0.3–0.7 units/mL determined by anti-factor Xa assay.)

Time	aPTT (seconds)	Heparin Dosage Order
0800	31 (baseline)	7,400 units bolus followed by 1,700 units/hour infusion
0900	130	Hold infusion for 30 minutes, then to 1,500 units/hour
1500	40	Rebolus with 2,400 units, then to 1,700 units/hour
2100	85	Continue at 1,700 units/hour; recheck aPTT every morning

Although the aPTT drawn 1 hour after the initiation of the maintenance infusion (9 AM) demonstrates excessive prolongation of the aPTT (130 seconds), this value is most likely explained by inappropriate timing of the test. When aPTT values are drawn too soon after a heparin bolus dose (i.e., before the maintenance infusion has achieved a steady state concentration in serum), they are predictably very high, but are not associated with a bleeding risk and do not accurately reflect the anticipated level of anticoagulation in the patient. To ensure accuracy, the clinician should obtain aPTT values no sooner than 6 hours after a bolus dose or any change in the infusion rate. Even results obtained at 6 hours may be excessively prolonged in some patients because of the dose-dependent pharmacokinetic characteristics of heparin.

J.T.'s heparin dose was decreased at 0900 based on this prolonged, yet inappropriately timed, value. A repeat aPTT at 3 PM was only 40 seconds. The decrease in the dosage to 1,500 units/hour and the repeat aPTT of 40 seconds reflect near steady state conditions because 6 hours has elapsed since the dosage change. Because the aPTT was subtherapeutic at 3 PM (40 seconds), administration of a smaller repeat bolus dose (2,000 units) and an increase in the maintenance infusion to 1,700 units/hour was the correct course of action. Subsequent aPTT values reflected therapeutic anticoagulation.

Dosing nomograms or protocols have been recommended for adjustment of heparin dosing based on aPTT results.[3,16] Nomogram-based dosing reduces the time to reach therapeutic range compared with empiric dosing.[22] Attaining a therapeutic aPTT in <24 hours has been shown to lower in-hospital and 30-day mortality rates.[23] After initiation based on patient weight, dosing adjustments may also be weight-based or may simply be made in international units per hour. A sample heparin dosing nomogram specific for a reagent with a therapeutic aPTT range of 60 to 100 seconds (and used in the adjustment of heparin doses for J.T.) is illustrated in Table 11-11.

Responses to changes in infusion rates of heparin are not always linear, and to some extent, heparin doses are adjusted by trial and error. As the patient's condition improves after several days and endothelialization of the clot occurs, heparin dosing requirements may decrease.

Therapeutic Monitoring

CASE 11-1, QUESTION 8: How should J.T.'s heparin therapy be monitored?

Once baseline clotting parameters have been established and a loading dose of heparin has been administered, the aPTT should be measured routinely to guide subsequent dosing adjustments. The aPTT should be evaluated no sooner than 6 hours after the loading dose or after any changes in infusion rate, as noted previously. If dosing is stable, the aPTT should be evaluated once daily (Table 11-11).

Additional monitoring parameters for heparin therapy include evaluation for potential adverse reactions and possible therapeutic failure. The Hgb and/or Hct and a platelet count should be checked every 1 to 2 days. J.T. should be examined for signs of bleeding, as well as for signs and symptoms associated with thrombus extension and PE. Finally, if unusual or unexpected aPTT results are reported, the clinician should consider the possible influence of solution preparation errors (see Chapter 2, Interpretation of Clinical Laboratory Tests), infusion pump failure, infusion interruption, and administration or charting errors in the assessment of J.T.'s heparin therapy.[24]

Duration of Therapy

CASE 11-1, QUESTION 9: How long should heparin therapy be continued in J.T. if the patient starts warfarin?

Adherence of a thrombus to the vessel wall and subsequent endothelialization usually takes 7 to 10 days. However, anticoagulation therapy must generally continue for 3 months to prevent recurrent thrombosis.[15] For many years, warfarin was preferred for this long-term anticoagulation because it can be administered orally, and it is generally initiated on the same day as heparin. The long elimination half-life of warfarin and the long elimination half-lives of clotting factors II and X necessitate a prolonged period of overlap between warfarin and heparin. Therefore, if warfarin is initiated, heparin is continued for a minimum of 5 days and until the INR is greater than 2.0 for 24 hours. If the INR exceeds the therapeutic range (i.e., INR > 3.0) prematurely, it is acceptable to stop parenteral therapy before the patient has received 5 days of treatment.[15]

Table 11-11

Sample Heparin Dosing Nomogram

1. Suggested loading dose
   - Treatment of DVT/PE: 80 units/kg (rounded to nearest 500 units)
   - Prevention, including cardiovascular indications: 70 units/kg (rounded to nearest 500 units)
2. Suggested initial infusion
   - Treatment of DVT/PE: 18 units/kg/hour (rounded to nearest 100 units)
   - Prevention, including cardiovascular indications: 15 units/kg/hour (rounded to nearest 100 units)
3. First aPTT check: 6 hours after initiating therapy
4. Dosing adjustments: per this chart (rounded to nearest 100 units)

aPTT[a] (seconds)	Heparin Bolus	Infusion Hold Time	Infusion Rate Adjustment	Next aPTT
<50	4,000 units	0	Increase by 200 units/hour	In 6 hours
50–59	2,000 units	0	Increase by 100 units/hour	In 6 hours
60–100	0	0	None	Every AM
101–110	0	0	Decrease by 100 units/hour	In 6 hours
111–120	0	0	Decrease by 200 units/hour	In 6 hours
121–150	0	30 minutes	Decrease by 200 units/hour	In 6 hours
151–199	0	60 minutes	Decrease by 200 units/hour	In 6 hours
>200	0	PRN	Hold until aPTT < 100	Every hour until <100

[a] Based on aPTT reagent-specific therapeutic range of 60–100 seconds corresponding to a plasma heparin concentration of 0.3–0.7 units/mL determined by anti-factor Xa activity.

aPTT, activated partial thromboplastin time; DVT, deep vein thrombosis; PE, pulmonary embolism; PRN, as necessary.

Adverse Effects

CASE 11-1, QUESTION 10: On day 2 of heparin therapy, J.T.'s complete blood count reveals a platelet count of 180,000/μL, decreased from 255,000/μL at baseline. What is a reasonable explanation for this thrombocytopenia and how should it be managed?

Thrombocytopenia

Thrombocytopenia induced by heparin has two distinct presentations.[5] Heparin-associated thrombocytopenia (HAT) occurs as a direct effect of heparin on platelet function, causing transient platelet sequestration and clumping with reductions in platelet count, but usually remaining greater than 100,000/μL. This reversible form of thrombocytopenia occurs within the first several days of heparin therapy. Patients remain asymptomatic, and platelet counts return to normal even when heparin therapy is continued. J.T.'s reduction in platelet count is somewhat modest and likely represents HAT. His platelet count should be monitored daily, and heparin therapy should be continued.

Reductions in platelet count of greater than 50% from baseline suggest the development of heparin-induced thrombocytopenia (HIT), a more severe immune-mediated reaction with a typical delay in onset of 5 to 10 days after the initiation of heparin therapy. In contrast, “rapid-onset” HIT can occur rapidly (within 24 hours of UFH initiation) and is strongly associated with recent heparin exposure. And “delayed-onset” HIT is associated with an onset of thrombocytopenia that begins several days after heparin has been stopped.[5]

Heparin use leads to the formation of immunoglobulin G (IgG) antibodies that recognize multimolecular complexes of a platelet protein called platelet factor 4 (PF4) and heparin that form on the surface of platelets.[5] Antibodies against PF4/heparin complexes are responsible for the prothrombotic nature of HIT due to their capability to induce platelet activation by cross-linking platelet Fcc receptor IIa (CD32a),[25] and release procoagulant, platelet-derived microparticles, resulting in a large generation of thrombin and the formation of venous and arterial thromboses. The diagnosis of immune-mediated HIT is made based on clinical findings supplemented by laboratory tests confirming the presence of platelet-activating anti-PF4/heparin antibodies.[5,26] The 4-T score is the most common pretest probability test that can be used to estimate the likelihood of HIT based on extent and timing of platelet count reduction, the presence of thrombus, and the possibility of other causes of thrombocytopenia (Table 11-12).[5,27]

The overall incidence of HIT is less than 3% after 5 days of UFH use, but the cumulative incidence can be as high as 6% after 14 days of continuous heparin use. Despite its low incidence, HIT is a life-threatening condition with a reported mortality rate of 5% to 10%. Venous thrombosis is the most common complication secondary to HIT, with rates reported at 2.4 to 1 more common than arterial thrombosis (limb artery thrombosis, thrombotic stroke, and myocardial infarction).[28] Limb gangrene has been reported at 5% to 10%, with a resulting risk of amputation.[29]

In patients who develop HIT, heparin therapy should be stopped immediately, and treatment with an alternative anticoagulant should be initiated.[5,30] Although associated with a lower risk of HIT (<1%) than UFH, LMWH products are contraindicated in patients with HIT because of a high incidence of immunologic cross-reactivity with heparin.[5] The future use of heparin in patients with HIT, especially in the first 3 months after the diagnosis, should be avoided. Treatment options include the direct thrombin inhibitors argatroban and bivalirudin, although only argatroban is approved for this indication by the FDA. The dose of argatroban is administered as an IV infusion due to its short half-life and should be titrated based on aPTT testing. Bivalirudin also appears to be a promising alternative for the treatment of HIT due to its short-half life, low immunogenicity, minimal effect on INR, and enzymatic metabolism. Various patient-related factors (such as the presence of renal or hepatic dysfunction; drug availability, cost, and institutional preference) should be used to select the most appropriate agent[5] (Table 11-7).

Table 11-12

The 4T Score: Pretest Probability of Heparin-Induced Thrombocytopenia

Category	2 Points	1 Point	0 Points
1. Thrombocytopenia	Platelet count fall >50% and platelet nadir ≥20 × 10^9 L^{-1}	Platelet count fall 30%–50% or platelet nadir 10–19 × 10^9 L^{-1}	Platelet count fall <30% or platelet nadir <10 × 10^9 L^{-1}
2. Timing of platelet count fall	Clear onset between days 5 and 10 or platelet fall ≤1 day (prior heparin exposure within 30 days)	Consistent with days 5–10 fall, but not clear (e.g., missing platelet counts) or onset after day 10 or fall ≤1 day (prior heparin exposure 30–100 days ago)	Platelet count fall < 4 days without recent heparin exposure
3. Thrombosis or other sequelae	New thrombosis (confirmed) or skin necrosis at heparin injection sites or acute systemic reaction after intravenous heparin bolus	Progressive or recurrent thrombosis or nonnecrotizing (erythematous) skin lesions or suspected thrombosis (not proven)	None
4. Other causes for thrombocytopenia	None apparent	Possible	Definite

Total Score <3 = low probability of HIT 4–5 = intermediate probability of HIT >6 = high probability of HIT.
Source: Lo GK et al. Evaluation of pretest clinical score (4 T's) for the diagnosis of heparin-induced thrombocytopenia in two clinical settings. J Thromb Haemost. 2006;4:759.

CASE 11-1, QUESTION 11: On day 3 of heparin therapy, J.T.'s Hct has dropped from a baseline of 37.5% to 28%, and the patient noted blood in his commode after urination. Describe an approach to evaluate and interpret this event.

Hemorrhage

Bleeding is the most common adverse effect associated with heparin. A summary of eight studies reporting heparin-associated bleeding found the absolute frequency of fatal, major, and all (major or minor) bleeding to be 0.4%, 6%, and 16%, respectively.[31] The corresponding average daily frequencies were 0.05% for fatal bleeding, 0.8% for major bleeding, and 2% for major or minor bleeding; cumulative risk increased with the duration of therapy. The most common sites for heparin-associated bleeding are soft tissues, the GI and urinary tracts, the nose, and the oral pharynx. The use of different criteria to define major versus minor bleeding accounts for much of the variability in reported frequency of bleeding among studies.

In addition to length of therapy, many factors influence the risk of bleeding during heparinization, including advanced age, serious comorbid illnesses (heart disease, renal insufficiency, hepatic dysfunction, cerebrovascular disease, malignancy, and severe anemia), and concomitant antithrombotic therapy.[31] The incidence of UFH-associated bleeding complications is minimal with SC prophylactic doses, but higher (2%–4%) with therapeutic doses given via IV infusion. Soft tissue bleeding commonly occurs at sites of recent surgery or trauma. Previously undiagnosed abnormalities, including malignancy and infection, may be identified in some patients with GI or urinary tract bleeding associated with heparin therapy.

The influence of the intensity of heparinization on bleeding risk is controversial. Although an elevated aPTT has historically been considered a risk factor for bleeding complications, several investigators have been unable to substantiate a relationship between supratherapeutic aPTT values and hemorrhagic effects.[3] In addition, bleeding episodes can occur when coagulation test results are within the therapeutic range. These conflicting results may be explained in part by the influence of additional risk factors for bleeding and by the effect of heparin on platelet function and vascular permeability.

J.T. has developed hematuria despite an acceptable intensity of anticoagulation. He should be questioned and examined for the presence of nose bleeding (epistaxis), increased tendency to bruise (ecchymosis), bright red blood in the stool (hematochezia), black or tarry stool (melena), or coughing up of blood (hemoptysis). Blood pressure and pulse, both sitting and standing, should be obtained to determine whether orthostasis representing blood loss is present. A thorough evaluation of the urinary tract may reveal a previously unknown abnormality that will explain the bleeding episode. Although his concurrent low-dose aspirin therapy may increase the risk of minor bleeding complications, aspirin therapy would not be discontinued due to his history of coronary artery disease.

CASE 11-1, QUESTION 12: What other side effects of heparin should be considered in J.T.?

Osteoporosis

The development of osteoporosis has been associated with administration of more than 20,000 international units/day of heparin for 6 months or longer.[32] Various mechanisms have been suggested, but the underlying pathophysiology of this rare adverse effect remains unclear. Affected patients may present with bone pain and/or radiographic findings suggestive of fractures. The possibility of osteoporosis should be considered in patients receiving long-term, high-dose heparin therapy such as pregnant patients, postmenopausal women, and elderly patients.

Hypersensitivity Reactions

Other rarely occurring adverse effects associated with heparin include generalized skin reactions that can progress to necrosis, alopecia, and hypersensitivity reactions, resulting in hypotension, nausea, and shortness of breath. In 2007, an increase in hypersensitivity reactions to heparin was attributed to oversulfated chondroitin sulfate in the heparin manufacturing process.[33]

Reversal of Effect

CASE 11-2

QUESTION 1: K.G. is a72-year-old woman with a DVT that occurred during her hospital stay. On day 4 of heparin therapy, she received a full bag of 25,000 units of heparin during a 1-hour period as a result of an infusion pump malfunction. The infusion was stopped and within 30 minutes, she became diaphoretic and hypotensive. Bright red blood was evident on rectal examination, and a large retroperitoneal mass was noted. How should the excessive heparin effect be reversed?

K.G. has definite signs of hemorrhage from the GI tract, a site of bleeding associated with considerable mortality. Heparin should be discontinued immediately, and treatment should include maintenance of fluid volume and replacement of clotting factors with whole blood, fresh frozen plasma, or clotting factor concentrates. If hemorrhage had not been present and the only manifestation of overdose had been a prolonged aPTT, administration of heparin simply could have been discontinued, permitting the effects to clear within a few hours.

Protamine can be used to neutralize heparin by forming an inactive protamine–heparin complex.[3] Protamine has a rapid onset of action, with effects lasting about 2 hours. Protamine sulfate is infused slowly over 3 to 5 minutes, as a 1% solution at a dose of 1 mg for each 100 international units of heparin administered in the last 2 to 3 hours. The maximum single recommended dose of protamine is 50 mg, but doses may be repeated if bleeding persists. Response to protamine therapy can be assessed by a return of the aPTT to baseline. Adverse effects associated with protamine include systemic hypotension secondary to rapid administration; anaphylaxis characterized by edema, bronchospasm, and cardiovascular collapse; and catastrophic pulmonary vasoconstriction[34] (see Chapter 32, Drug Hypersensitivity Reactions).

Outpatient Treatment of DVT

CASE 11-3

QUESTION 1: N.C. is a 32-year-old woman who presents to the emergency department (ED) complaining of right leg pain behind the right knee of 2-day duration. She denies recent injury, but her medication history reveals that she recently started combination oral contraceptive tablets. She has no significant medical history and has no family history of clotting disorders. A duplex ultrasound is positive for DVT and immediate anticoagulation is indicated. What therapeutic alternatives to hospitalization for IV UFH are available for this patient?

In the past, UFH was the initial treatment of choice for acute DVT; however, LMWHs and fondaparinux are now becoming more convenient and practical treatment alternatives to UFH.[15] These agents, administered SC and without the need for routine coagulation monitoring, allow patients to be treated at home while transitioning to therapeutic warfarin. In addition, meta-analysis data suggest that LMWH therapy for acute VTE results in fewer deaths, major hemorrhages, and recurrent VTE when compared to UFH.[35] Based on these advantages, outpatient use of LMWH has become the most common approach to treatment of uncomplicated DVT in patients that transition to warfarin. Home treatment is safe and effective and improves the overall physical and social functioning of patients being treated for DVT.[36] The drug costs associated with LMWH treatment are much higher than the costs of IV UFH, but overall costs to healthcare systems are significantly reduced when patients can be treated at home rather than in the hospital.[37,38] Fondaparinux can also be considered as an alternative treatment as it has been shown to be as effective and safe as LMWH in the treatment of DVT.[39] Additionally, weight-based SC UFH (initial dose of 333 international units/kg followed by 250 international units/kg every 12 hours) without routine aPTT monitoring while patients become therapeutic on warfarin is an alternative for the treatment of acute VTE.[40] Vials of UFH at a concentration of 20,000 international units/mL are used by the pharmacy or the patient to draw up the weight-based dose. Although routine aPTT monitoring is not necessary, platelet count monitoring during the first 2 weeks is required to evaluate the possible development of HIT.

For N.C. to be treated at home with LMWH, she or a family member must be willing and able to administer SC injections, and she must be able to return for frequent follow-up visits, particularly during the first few weeks while warfarin therapy is initiated. In addition, her healthcare insurance should cover the cost of the drug, or she must be able to pay out of pocket. Contraindications to outpatient treatment of VTE include a preexisting condition that requires hospitalization, clinical symptoms of PE with hemodynamic instability, and recent or active bleeding.

N.C. meets the eligibility requirements for home treatment of her DVT. She is also a suitable candidate for a DOAC and prefers to not have to perform self-injections of medication. Currently, there are two DOACs, rivaroxaban and apixaban, approved in the United States for monotherapy and do not require an initial period of parenteral anticoagulant. Advantages to the use of a DOAC compared to warfarin include the lack of routine monitoring for assessing drug efficacy, fewer drug and food interactions, and a lower rate of major bleeding compared to warfarin. Currently, only dabigatran has an FDA-approved agent for reversal, idarucizumab, and there are several other reversal agents in clinical trials. The lack of reversal agent leaves some providers and patients apprehensive to their use. When selecting a DOAC, it is important to know the patient’s renal function because these agents have varying doses based on current renal function. A baseline CBC should also be checked, because all anticoagulants have the potential for bleeding, and it is important to know the baseline hemoglobin level in case bleeding occurs on treatment. In this case, N.C. received an injection of LMWH while in the emergency department, and rivaroxaban is selected for monotherapy, at 15 mg twice daily with food for 21 days, followed by 20 mg daily with food for the remainder of her 3-month duration of treatment. N.C. should be advised to follow up with her primary care provider regarding her new diagnosis, and it should be stressed to the patient the importance of proper transitioning of the dose from the twice a day to the once a day schedule. Anticoagulation clinics may also be involved in N.C.'s care to follow up and make sure she was able to obtain the medication without insurance barriers, that the DOAC dose was appropriate, that her DVT symptoms are improving, that she is tolerating the medication, and that she transitions to the correct dose appropriately.[41] Higher risk patients, such as those with lower health literacy and multiple medical problems, may benefit from face-to-face clinical visits if this information cannot be obtained by telephone. Centralized anticoagulation services are expanding beyond traditional monitoring to include patients on DOACs by prospectively following them to ensure optimal therapeutic outcomes. There are some cases where it may be necessary to test whether the DOAC is present, such as in a patient with acute stroke, need for urgent surgery, or in the case of major bleeding.[42] There is no current consensus on how best to do this, because the tests that correlate the best are not often readily available. Of those that are readily available, aPTT or thrombin time are often used to detect dabigatran presence, and the prothrombin time or anti-factor Xa calibrated for the factor Xa inhibitors.[42]

Table 11-13

Dosing of Low-Molecular-Weight Heparin and Fondaparinux for the Treatment of Venous Thromboembolism

Dalteparin	Enoxaparin	Tinzaparin	Fondaparinux
100 international units/kg SC every 12 hours OR 200 international units/kg SC every 24 hours	1 mg/kg SC every 12 hours OR 1.5 mg/kg SC every 24 hours	175 international units/kg SC every 24 hours	5 mg SC every 24 hours if weight <50 kg 7.5 mg SC every 24 hours if weight 50–100 kg 10 mg SC every 24 hours if weight >100 kg

SC, subcutaneously.

CASE 11-3, QUESTION 2: During a follow-up call to N.C. from the anticoagulation clinic the next morning, it is discovered that N.C. was not able to get the rivaroxaban filled at her pharmacy last night because her insurance does not cover any DOAC therapy without first documenting a treatment failure to warfarin. What alternative treatment is available for N.C?

Before the DOACs, treatment with self-injected LMWH bridging to warfarin at home was the standard of care. Possible treatment options and doses for N.C. are listed in Table 11-13. In this case, enoxaparin is the LMWH preferred by her insurance because it is available generically. The usual dosing of enoxaparin for treatment of DVT is 1 mg/kg total body weight SC every 12 hours, rounded to the nearest 10-mg increment. Once-daily dosing at 1.5 mg/kg SC every 24 hours is also an option, but this strategy is inferior to twice-daily dosing in patients with malignancy or obesity.[43] N.C.'s medical history is suitable for the once-daily dose of enoxaparin, which is more convenient for administration. At 65 kg, a dose of 1.5 mg/kg would be 97.5 mg, which will be rounded to the nearest 10-mg increment. N.C. will therefore receive 100 mg SC every 24 hours. Warfarin therapy is initiated concurrently to expedite the conversion to oral treatment.

Because LMWHs are eliminated renally, patients with significant renal impairment require dose reductions to prevent drug accumulation and to minimize the risk of bleeding complications.[44] The degree of drug accumulation can vary between the various LMWH preparations, and thus specific guidelines for dose adjustments are agent specific (Table 11-14).[45] Some experts suggest monitoring of anti-factor Xa activity to rule out accumulation of LMWHs in patients with renal impairment who are on treatment for extended periods of time (i.e., greater than 1 week).[45,46] Fondaparinux is also renally excreted and is contraindicated in patients with creatinine clearance less than 30 mL/minute.

N.C. should be educated regarding the potential adverse effects of LMWH therapy (bleeding, thrombocytopenia, pain and bruising at the injection site), required laboratory monitoring, and the expected duration of anticoagulation. At baseline, Hgb and/or Hct, INR, serum creatinine (SCr), and platelet count should be determined. Platelets will continue to be monitored at least every 2 to 3 days while the patient is receiving LMWH therapy, to a maximum of 10 to 14 days. N.C. can expect to continue enoxaparin therapy for a minimum of 5 days. If by day 5 her INR is therapeutic and stable, enoxaparin can be discontinued. Oral anticoagulation with warfarin should be continued for 3 months.[15] N.C. should also be advised against further use of estrogen-containing contraceptives.[47]

To ensure the safety and efficacy of home treatment, N.C. should be provided with the names and telephone numbers of the healthcare providers who will assume responsibility for her care, including her primary physician and her anticoagulation management team. No patient should be sent home with LMWH without an adequate follow-up plan.

Table 11-14

Dosing of Low-Molecular-Weight Heparins in Patients with Renal Impairment (CrCl < 30 mL/minute)[a]

LMWH	Dalteparin	Enoxaparin	Tinzaparin
Product information recommendations	Use with caution	Prophylaxis—30 mg SC daily	Use with caution

		Treatment—1 mg/kg SC daily	
Dosing suggestions based on agent-specific pharmacokinetic observations	CrCl < 30 mL/minute[a]: no dose adjustment needed up to 1 week with prophylactic doses For use longer than 1 week, consider monitoring of anti-Xa activity and adjust dose if accumulation is noted CrCl 30–50 mL/minute: no dose adjustment needed	CrCl <30 mL/minute[a]: Consider a 40%–50% dose decrease and subsequent monitoring of anti-Xa activity CrCl 30–50 mL/minute: Consider a 15%–20% dose decrease with prolonged use (longer than 10–14 days) and subsequent monitoring of anti-Xa activity	CrCl <30 mL/minute[a]: consider a dose decrease of 20% and subsequent monitoring of anti-Xa activity CrCl 30–50 mL/minute: no dose adjustment needed

[a] In patients with a CrCl <30 mL/minute, data are very limited and use of unfractionated heparin is suggested.

Prevention of Venous Thromboembolism

CASE 11-4

QUESTION 1: M.G., a 63-year-old obese man, is to undergo elective abdominal surgery for treatment of an umbilical hernia. He has a medical history significant for hypertension, currently controlled by enalapril 10 mg daily (blood pressure, 130/80 mm Hg), and gout, controlled with allopurinol 300 mg daily. What therapeutic interventions might decrease the risk of DVT or PE in M.G.?

Surgical procedures represent a significant risk factor for DVT formation. However, all hospitalized patients, including both surgical and nonsurgical/medical patients, should be stratified for risk of VTE based on the presence of various factors.[12,48–50] Risk stratification is used to select the most appropriate therapeutic interventions to prevent DVT and thereby reduce the risk of fatal PE. These interventions include both mechanical and pharmacologic strategies.

NONPHARMACOLOGIC MEASURES

Mechanical interventions aimed at preventing venous stasis and increasing venous return include the use of elastic compression stockings, as well as leg elevation, leg exercises, and early postoperative ambulation. Intermittent pneumatic compression (IPC) of the leg muscles, using inflatable cuffs applied to the calf and thigh, represents another alternative for the prevention of DVT.[12] Because it is generally less effective than pharmacologic prophylaxis, mechanical prophylaxis is most commonly used in patients at high risk of bleeding, or as an adjunct to pharmacologic prophylaxis in patients at very high risk for VTE.

PHARMACOLOGIC MEASURES

Fixed, low-dose unfractionated heparin (LDUFH), administered as 5,000 units SC every 8 to 12 hours depending on the indication, is an inexpensive and effective pharmacologic approach to DVT prevention in the setting of venous stasis in patients with acute medical illness, or after certain surgical procedures. Because LDUFH inactivates factor Xa without a direct effect on factor IIa, the aPTT is not prolonged, and therefore aPTT monitoring is unnecessary. Bleeding complications are minimized using this dosing regimen.

Fixed-dose SC LMWH and fondaparinux are alternative approaches for preventing DVT. Enoxaparin 30 mg SC every 12 hours or 40 mg SC once daily, dalteparin 2,500 to 5,000 international units SC once daily, and fondaparinux 2.5 mg SC once daily are effective strategies, although enoxaparin has been studied for a larger number of indications. The DOACs rivaroxaban, apixaban, and dabigatran have been FDA-approved for DVT prophylaxis in orthopedic surgery patients. Betrixaban 160 mg as a single dose followed by 80 mg daily is approved for VTE prophylaxis in adult patients hospitalized for an acute medical illness. Current recommendations for prevention of VTE based on risk stratification are presented in Table 11-15.[12,48,49]

M.G. is at high risk for DVT and PE, not only because of general surgery but also because of his age (older than 40 years) and the presence of other risk factors for VTE (obesity, and probable postoperative immobilization). Options for DVT prevention include SC heparin at 5,000 international units every 8 hours or a LMWH (enoxaparin 40 mg SC daily, or dalteparin 2,500 international units initial dose followed by 5,000 international units SC daily). The first dose should be administered several hours preoperatively, and dosing should continue postoperatively until he is fully ambulatory. If bleeding risk is of concern, IPC could be used as an alternative. VTE prophylaxis is typically continued until hospital discharge, but may be continued for up to 30 days in certain high-risk populations, including patients with cancer, orthopedic surgery, bariatric surgery, or with a prior history of VTE.

PULMONARY EMBOLISM

Clinical Presentation

CASE 11-5

QUESTION 1: A.W. is a 52-year-old, 70-kg woman. She recently returned from a 12-hour car ride where she only stopped to stretch twice. Yesterday she noticed a swollen right calf that is painful and warm. This swelling gradually increased, affecting the entire right leg to the groin, and prompted her to seek medical attention. In the ED, she also notes the recent onset of right-sided pleuritic chest pain without SOB or hemoptysis. Her medical history includes a gastric ulcer 4 years ago, treated with proton pump inhibitor therapy, that has not recurred. Physical examination reveals an enlarged right leg and moderate tenderness in the entire leg. Chest examination reveals labored respirations, equal breath sounds, and no wheezing or crackles. Vital signs include blood pressure, 160/90 mm Hg; heart rate, 100 beats/minute; and respiratory rate, 28 breaths/minute and regular. Laboratory data include the following:

Hct, 26.7%
SCr 1.1 mg/dL
Arterial blood gases (on room air)
  PO_2, 72 mm Hg (normal, 75–100)
  PCO_2, 30 mm Hg (normal, 35–45)
  pH 7.48 (normal, 7.35–7.45)

Chest CT shows a pulmonary embolism in the distal right main pulmonary artery extending into the right lower lobe. The electrocardiogram (ECG) shows sinus tachycardia. The lower extremity duplex ultrasound is positive for acute occluding thrombus from the right femoral vein all the way down to the soleal vein. Coagulation test results include the following:

PT, 11.2 seconds (INR, 1.0)
aPTT, 28 seconds
Platelet count, 248,000/µL

What subjective and objective evidence in A.W. is consistent with PE?

SIGNS AND SYMPTOMS

The clinical diagnosis of PE is often difficult to make because of the nonspecificity of symptoms.[51,52] The most common symptoms of PE include tachypnea, cough, substernal and pleuritic chest pain, dyspnea, hemoptysis, fever, and unilateral leg pain. Signs and symptoms such as hypotension, tachycardia, presence of B-type natriuretic peptides (BNP) or NT-pro-BNP (N-terminal pro-brain natriuretic peptide), troponins (I or T), hypoxia, and electrocardiogram (ECG) changes suggestive of right ventricular strain are important to recognize as these may indicate more severe thromboembolism and increased risk for 30-day mortality.[53] DVT precedes PE in 80% or more of patients. A combination of these signs and symptoms provides further evidence for acute PE.

DEFINITIONS

There are varying ways to define the severity of a PE. Some define PE based on a patient's in-hospital or 30-day risk for mortality, whereas other literature will cite terms such as massive and submassive PE.[53,54] Low-risk PE is classified as the presence of thromboembolism without changes in hemodynamics, right ventricular function, or cardiac biomarkers. These types of patients can also be classified as small-to-moderate PE. High-risk PE is defined by the presence of shock (manifesting as tissue hypoperfusion, and hypoxia, cool clammy extremities, alterations in consciousness) or hypotension, specifically defined as: a systolic blood pressure $<$ 90 mm Hg or a $\geq$ 40 mm Hg drop in systolic blood pressure for $>$ 15 minutes which is not attributed to new onset arrhythmia, hypovolemia, or sepsis. These patients can also be classified as having massive PE.[54] Patients with right ventricular dysfunction characterized by echocardiographic evidence or by positive cardiac biomarkers (BNP $>$ 90 pg/mL or NT-pro BNP $>$ 500 pg/mL, Troponin I $>$ 0.4 ng/mL, Troponin T

> 0.1 ng/mL) are classified as having submassive PE if they are hemodynamically stable.[54]

Table 11-15

Prevention of Venous Thromboembolism[12,48]

General and Abdominal–pelvic Surgery[a]	
Very low risk for VTE	Early and frequent ambulation
Low risk for VTE	IPC over no prophylaxis
Moderate risk for VTE not at high risk for MB	LMWH and LDUFH over no prophylaxis. IPC over no prophylaxis
Moderate risk for VTE & high risk for MB	IPC over no prophylaxis
High risk for VTE and not at high risk for MB	LMWH or LDUFH over no prophylaxis. IPC or elastic stockings can be added
High risk for VTE undergoing surgery for cancer and not otherwise at high risk for MB	Extended prophylaxis with LMWH (4 weeks) over limited duration
High risk for VTE and high risk for MB	IPC over no prophylaxis until bleeding risk diminishes then initiate pharmacologic prophylaxis
High risk for VTE unable to receive LMWH or LDUFH and not at high risk for MB	IPC over no prophylaxis
General and abdominal–pelvic surgery patients	IVC filter should not be used for primary VTE prevention Periodic surveillance with venous compression ultrasound should not be performed
Orthopedic Surgery	
Hip or knee replacement	Minimum of 10–14 days of one of the following: LMWH (preferred), fondaparinux, apixaban, dabigatran, rivaroxaban, LDUFH, warfarin (INR 2–3), or aspirin.
Hip fracture surgery	Minimum of 10–14 days of one of the following: LMWH, fondaparinux, LDUFH, warfarin (INR 2–3), or aspirin. LMWH preferred over warfarin or aspirin
Major orthopedic surgery	Dual prophylaxis with antithrombotic and IPC during hospital stay. Extended prophylaxis up to 35 days suggested.
Cardiac Surgery	Uncomplicated course: IPC over no prophylaxis Prolonged stay: add LDUFH or LMWH to IPC
Thoracic Surgery	
Moderate risk for VTE & not at high risk for MB	LMWH or LDUFH
High risk for VTE & not at high risk for MB	LMWH or LDUFH ±IPC
High risk for MB	IPC until bleeding risk diminishes, then pharmacologic prophylaxis

Trauma[b]	LMWH or LDUFH. Add IPC if high risk for VTE and use IPC if unable to take LMWH or LDUFH
Acutely Ill Hospitalized Medical Patients	
With increased risk of thrombosis	LMWH, LDUFH BID, LDUFH TID, fondaparinux, or betrixaban
With low risk of thrombosis	No pharmacologic or mechanical prophylaxis
With bleeding or at high risk of MB	No anticoagulant thromboprophylaxis
With increased risk of thrombosis and at high risk of MB	GCS, IPC. When bleeding risk decreases, start pharmacologic thromboprophylaxis instead of mechanical thromboprophylaxis

[a] includes gastrointestinal, urologic, gynecologic, bariatric, vascular, or plastic and reconstructive surgery.

[b] includes traumatic brain injury, acute spinal injury, and traumatic spine injury.

BID, twice daily; GCS, graduated compression stockings; INR, international normalized ratio; IPC, intermittent pneumatic compression; LDUFH, low-dose unfractionated heparin (5,000 international units subcutaneously every 8–12 hours); LMWH, low-molecular-weight heparin (enoxaparin 40 mg subcutaneously daily or 30 mg SC every 12 hours; dalteparin 2,500–5,000 international units subcutaneously daily); fondaparinux (2.5 mg subcutaneously daily); VTE, venous thromboembolism; MB, major bleeding; AC, anticoagulation.

DIAGNOSIS

Because the clinical signs and symptoms of PE are difficult to distinguish from many other medical conditions, further evaluation is necessary.[51,52] Chest radiograph, ECG, and arterial blood gas (alveolar-arterial oxygen gradient) abnormalities are often present in patients with PE, but like clinical signs and symptoms, they are somewhat nonspecific. Pulmonary imaging is necessary to diagnose or definitely rule out PE. Although many methods are clinically available for chest imaging, the computed tomographic (CT) pulmonary angiography and ventilation–perfusion lung scanning (V/Q scan) are the most common tests used for the diagnosis of PE, with the multi-detector CT (MDCT) being the imaging test of choice because of its ability to visualize the pulmonary arteries in the greatest detail. Lung scans that incorporate an assessment of perfusion, or regional distribution of pulmonary blood flow, and ventilation are referred to as V/Q scans; they involve both the injection and the inhalation of radiolabeled compounds. Test results are expressed as a high, intermediate, or low probability of PE. When ventilation (air movement) is normal over an area that shows abnormal perfusion (blood flow), a V/Q mismatch exists, and PE is highly probable. If a matched defect is noted (abnormal ventilation over an area of abnormal perfusion), another disease state, such as chronic obstructive airway disease, is more likely.

As in the case of DVT, clinical assessment of PE can improve the diagnostic accuracy of noninvasive tests such as CT, MRI, or V/Q scanning. Validated assessment tools can be used to stratify a patient's probability of a PE[55–58] (Table 11-16). In patients with a low clinical probability of PE, measuring a high-sensitivity D-dimer can be considered, and, if negative, PE can be ruled out, eliminating the need of further imaging studies.[59] In patients with a moderate-to-high clinical probability of PE, diagnostic imaging studies should be performed.

Treatment

CASE 11-5, QUESTION 2: What anticoagulant strategy should be initiated for A.W.?

When the diagnosis of PE is suspected, anticoagulation should be initiated immediately while awaiting results of more definitive diagnostic procedures. There are several agents that can be used for the acute treatment of PE. IV UFH therapy initiated with a loading dose followed by a continuous infusion was the mainstay of therapy for many years. Alternatively, SC UFH can be used. However, if there is a concern about adequate SC absorption or in patients in whom fibrinolytic therapy is being considered, initial treatment with IV UFH is preferred to the SC route.[15] LMWHs are noninferior to UFH in the management of PE and are recommended over UFH in stable PE patients because of their ease of use, less major bleeding, and ability for outpatient management or early discharge.[60,61] Fondaparinux demonstrated noninferiority when compared with IV UFH for rate of recurrent PE, with similar rates of major bleeding.[62] More recently, the DOACs have been evaluated for both the initial and long-term management of VTE, with dabigatran, rivaroxaban, apixaban, and edoxaban all FDA-approved for the initial management of PE. All of the DOACs were compared to LMWH/VKA and found to be noninferior for the rate of recurrent VTE.[63–67] Rivaroxaban and apixaban were studied as monotherapy, whereas dabigatran and edoxaban patients were initially treated with at least 5 days of parenteral therapy prior to receiving a DOAC. If A.W. is being kept in the hospital for observation because of the severity of her symptoms, UFH therapy could be started at a loading dose of 5,600 units (80 international units/kg × 70 kg), followed by continuous infusion of 1,300 units/hour (18 units/kg/hour × 70 kg). Monitoring of the aPTT would be used to adjust dosing to maintain treatment within the therapeutic range (Table 11-11).

Alternatively, SC LMWH 70 mg every 12 hours (1 mg/kg every 12 hours × 70 kg) or SC fondaparinux 7.5 mg daily may be given while transitioning the patient to warfarin (Table 11-13). A.W. could receive fixed-dose enoxaparin 70 mg SC every 12 hours (1 mg/kg every 12 hours × 70 kg) or dalteparin 15,000 international units SC every 24 hours (200 international units/kg, rounded to nearest syringe size). Use of initial therapies such as LMWH, fondaparinux, and DOACs allows for outpatient therapy and early discharge in hospitalized patients with acute PE. For patients with low-risk PE and home circumstances that are adequate, early discharge is suggested over standard discharge.[15]

Table 11-16

Original and Simplified Pulmonary Embolism Severity Index (PESI) Scoring Systems

Parameter	Original Scoring Version (Points)	Simplified Scoring Version (Points)
Age	Points = age, (years)	1 (if age > 80 years)
Male sex	10	—
Cancer	30	1
Chronic heart failure	10	1[a]
Chronic pulmonary disease	10	1[a]
Heart rate > 110 BPM	20	1
Systolic blood pressure < 100 mm Hg	30	1
Respiratory rate > 30 breaths/minute	20	—
Temperature < 36°C	20	—
Altered mental status	60	—
Arterial oxygen saturation < 90%	20	1
30-Day Mortality Risk		
Very low: 0%–1.6%	Class I: < 65 points	0 points: 1%
Low: 1.7%–3.5%	Class II: 66–85 points	
Moderate: 3.2%–7.1%	Class III: 86–105 points	
High: 4%–11.4%	Class IV: 106–125 points	≥1 point: 10.9%
Very High: 10–24.5%	Class V: >125 points	

[a] only 1 point can be obtained for chronic heart failure and/or chronic pulmonary disease. Patients with both of these comorbidities can obtain only 1 point.

BPM, beats per minute; mm Hg, millimeters of mercury.

Source: Aujesky D et al. Derivation and validation of a prognostic model for pulmonary embolism. Am J Respir Crit Care Med. 2005;172:1041–1046; Jimenez D et al. Simplification of the pulmonary embolism severity index for prognostication in patients with acute symptomatic pulmonary embolism. Arch Intern Med. 2010;170:1383–1389.

Fibrinolytic therapy reverses right ventricular dysfunction and restores pulmonary perfusion more rapidly than anticoagulant therapy alone. It is generally reserved for patients with a high risk for mortality and a low risk for bleeding.[53] Percutaneous catheter-directed treatment provides localized delivery of fibrinolytics to the pulmonary thrombi and is an alternative invasive method for removal of pulmonary emboli. It is a less invasive approach compared to surgical embolectomy in patients who are not candidates for systemic fibrinolytic therapy. For patients with moderate-to-high-risk PE, catheter-directed thrombolysis has emerged as a promising option for patients who would also be candidates for systemic fibrinolytic therapy.[53]

WARFARIN

Transition from Injectable Anticoagulant Therapy

CASE 11-5, QUESTION 3: If A.W. is to start on warfarin, rather than a DOAC, when should it be administered, and how should the transition from injectable anticoagulant therapy be accomplished?

As in the treatment of DVT, if warfarin is to be started, the use of heparin, LMWH, or fondaparinux therapy for PE treatment should be continued for at least 5 days and until warfarin therapy is therapeutic for at least 24 hours. Warfarin should be started on the first day of treatment and continued for 3 months, or longer if indicated. However, a delay in the initiation of warfarin may be acceptable in the setting of an anticipated extended hospitalization, recent or anticipated surgery or other invasive procedures, or a medical condition with the potential for uncontrolled bleeding.[15]

There are several reasons to overlap heparin/LMWH/fondaparinux and warfarin therapy.[6] The onset of warfarin activity depends not only on its inherent pharmacokinetic characteristics (half-life > 36 hours), but also on the rate of elimination of circulating clotting factors. Although warfarin inhibits production of the vitamin K dependent clotting factors, previously synthesized clotting factors must be eliminated at rates that correspond with their elimination half-lives (Table 11-8). Approximately four half-lives are required for these factors to reach a new steady state after their production is inhibited, so the effect of warfarin can be delayed for several days. Initial increases in the INR reflect only reductions in factor VII activity, but full anticoagulation with warfarin requires adequate suppression of factors II and X, which have significantly longer elimination half-lives. By overlapping a quick onset injectable anticoagulant such as heparin/LMWH/fondaparinux with warfarin therapy, adequate anticoagulation can be continued until warfarin therapy reaches a therapeutic intensity.

In addition to suppressing the synthesis of the vitamin K-dependent clotting factors, warfarin also inhibits the formation of the naturally occurring anticoagulant protein C and its cofactor, protein S. In patients with congenital protein C or protein S deficiency, initial warfarin therapy can suppress these proteins to concentrations that may result in hypercoagulability with possible thrombus extension, unless concurrent heparin therapy provides adequate anticoagulation. To prevent these complications, heparin/LMWH/fondaparinux and warfarin therapy should overlap.

Heparin therapy has been observed to prolong the INR,[68] and warfarin can prolong the aPTT by several seconds.[69] Thus, interference with laboratory tests should be considered in the evaluation of the intensity of anticoagulation during the overlap of heparin and warfarin therapy.

Initiation of Warfarin Therapy

CASE 11-5, QUESTION 4: In an effort to discharge A.W. from the hospital as soon as possible, an initial dose of warfarin 10 mg PO every evening for 3 days has been ordered. Is such a "loading dose" reasonable? What are more effective approaches to initiating therapy?

Initiation of warfarin dosing is complex because dosing requirements vary significantly among individuals. Daily doses as low as 0.5 mg and as high as 20 mg or more may be required in individual patients to reach a therapeutic INR.[70] Two primary methods for initiation of warfarin therapy are used.[71] The average daily dosing method relies on an understanding that although dosing requirements for warfarin vary significantly among patients, an average dosing requirement of 4 to 5 mg/day of warfarin is necessary to maintain an INR of 2.0 to 3.0 in most patients. When average daily dosing is used for initiation of warfarin therapy, patients are typically started at 4 to 5 mg daily, with dosing adjustments as necessary until the therapeutic goal is reached. However, patients who may be more sensitive to the effects of warfarin (Table 11-17) are expected to require lower dosages of warfarin. In these patients, therapy should be initiated at 1 to 3 mg daily, with subsequent dosing adjustments as necessary. Several dosing algorithms, using a 4-mg to 5-mg initiation dose, have been developed to aid with dosing decisions after the first few doses of warfarin have been administered.[72–74] Another popular dosing algorithm recommended by the American College of Chest Physicians (ACCP) for outpatients uses a 10-mg initiation dose for the first 2 days, with the INR on day 3 measured to guide dosing on days 3 and 4, and the INR on day 5 used to guide the next three doses[21,75] (Fig. 11-4). Although using this dosing algorithm helps achieve a therapeutic INR more quickly than using a 5-mg initial dose, these findings may not be generalizable to all patient populations because the patients evaluated were relatively healthy, young outpatients.[76] The 10-mg initiation dose may lead to overanticoagulation and heightened bleeding risk in elderly and ill patients with multiple medical problems.[77] Average daily dosing is often used to initiate therapy in ambulatory patients; in this case, the first INR should be evaluated within 3 to 5 days of initiation of warfarin therapy (Table 11-18). In hospitalized patients, it is more common to evaluate the INR daily during initiation of therapy.

Table 11-17

Factors that Increase Sensitivity to Warfarin

Age older than 75 years
Weight < 45 kg
Clinical congestive heart failure
Clinical hyperthyroidism
Decreased oral intake
Diarrhea
Drug–drug interactions
Elevated baseline INR (>1.4)

End-stage renal disease
Fever
Hepatic disease
Hypoalbuminemia
Known CYP2C9 or VKORC1 variant
Malignancy
Malnutrition
Postoperative status

INR, international normalized ratio.

Flexible initiation of warfarin is an alternative approach for starting therapy that is based on evaluating the rate of increase in the INR and making daily dosing adjustments based on daily INR evaluation, with a goal of determining the eventual maintenance dosing requirement. A popular flexible initiation nomogram is presented in Table 11-19.[78,79] Using this nomogram, warfarin can be initiated with either a 10-mg or a 5-mg starting dose, with daily dosing adjustments based on the rate of increase in the INR. Flexible initiation does not necessarily shorten the time to reach the goal INR, and initiating therapy with a 10-mg dose as described in some protocols may be associated with an increased risk of early overanticoagulation in certain patients. Nonetheless, these methods offer a more individualized approach to initiation of therapy.

	Days/dose (mg)			Days/dose (mg)		
Day-3 INR	3	4	Day-5 INR	5	6	7
<1.3	15	15	<2.0	15	15	15
1.3–1.4	10	10	2.0–3.0	7.5	5	7.5
			3.1–3.5	0	5	5
			>3.5	0	0	2.5
1.5–1.6	10	5	<2.0	7.5	7.5	7.5
1.7–1.9	5	5	2.0–3.0	5	5	5
			3.1–3.5	2.5	2.5	2.5
			>3.5	0	2.5	2.5
2.0–2.2	2.5	2.5	<2.0	15	5	5
2.3–3.0	0	2.5	2.0–3.0	2.5	5	2.5
			3.1–3.5	0	2.5	0
			>3.5	0	0	2.5
>3.0	0	0	<2.0	2.5	2.5	2.5
			2.0–3.0	2.5	0	2.5
			3.1–4.0	0	2.5	0
			>4.0	0	0	2.5

Figure 11-4 Warfarin initiation dosing algorithm based on starting with 10-mg doses on days 1 and 2. (Source: Kovacs MJ et al. Prospective assessment of a nomogram for the initiation of oral anticoagulant therapy for outpatient treatment of venous thromboembolism. Pathophysiol Haemost Thromb. 2002;32:131.)

The baseline INR for A.W. was 1.0. Using the flexible initiation protocol presented in Table 11-19, the first dose of warfarin should be 10 mg administered in the evening on the first day of hospitalization. Subsequent INR values obtained daily will guide dosing requirements until a therapeutic INR is reached. The order for warfarin 10 mg orally every evening for three doses should be discontinued and replaced with daily orders for warfarin and INR monitoring.

Table 11-18

Warfarin Initiation for Outpatients Using the Average Daily Dosing Method

	Nonsensitive Patients	Sensitive Patients[a]

Initial dose	5 mg daily	2.5 mg daily
First INR	3 days	3 days
<1.5	7.5–10 mg daily	5–7.5 mg daily
1.5–1.9	5 mg daily	2.5 mg daily
2.0–3.0	2.5 mg daily	1.25 mg daily
3.1–4.0	1.25 mg daily	0.5 mg daily
>4.0	Hold	Hold
Next INR	2–3 days	2–3 days
Subsequent dosing and monitoring	Continue dose escalation and frequent monitoring until lower limit of therapeutic range is reached.	

Warfarin Use in Adults: Clinical Care Guideline, University of Illinois Hospital and Health Sciences System.

Intensity and Duration of Therapy

CASE 11-5, QUESTION 5: What is the goal INR for A.W. and how long should anticoagulation be continued?

In patients with DVT or PE, warfarin doses that prolong the PT to an INR of 2.0 to 3.0 are defined as regular intensity therapy. This therapeutic range is recommended to maximize the antithrombotic effect of warfarin while minimizing potential bleeding complications associated with excessive anticoagulation.[6] Once formed, venous clots adhere to the blood vessel wall. Thus, the first step in resolution of a thrombus involves covering the clot with a layer of endothelial cells to prevent additional platelet aggregation at the site of vessel injury. This endothelialization process generally takes 7 to 10 days to be completed. Initial anticoagulant treatment is used to prevent clot extension while allowing adequate endothelialization to occur. Continued anticoagulation prevents further clotting.

The appropriate duration of warfarin therapy is based on the likelihood of a recurrent venous thromboembolic event and the risk of bleeding in each patient (Table 11-9). Patients with unprovoked (idiopathic) DVT or PE should be treated for at least 3 months, but considered for indefinite therapy as their likelihood of having a recurrent event can be as high as 30% over 5 years.[15] Patients with DVT or PE associated with transient or reversible risk factors

---

(provoked VTE) are usually treated for 3 months, as in the case of A.W., whose VTE provoking risk factor was a prolonged car ride, as the risk of recurrence is lower (approximately 10% over 5 years). In cancer-associated thrombosis, first-line treatment consists of long-term LMWH based on improved clinical outcomes over warfarin; however, this needs to consider individual patient bleeding risk, patient preferences, tolerability, and drug costs.[80–86] The use of DOACs in patients with cancer is not currently endorsed; however, current data support its safety compared to other options.[87]

Adverse Effects

CASE 11-5, QUESTION 6: What possible adverse effects from oral anticoagulation therapy should be considered in A.W. and how should they be monitored?

Hemorrhage

Bleeding is the most common adverse effect associated with anticoagulation. A summary of experimental and observational inception cohort studies determined that the average annual frequency of fatal, major, and all (major or minor) bleeding in patients treated with warfarin was 0.6%, 3%, and 9.6%, respectively.[31] However, wide variation in bleeding frequencies has been reported, likely due to differences in patient characteristics, treatment protocols, and the definition and assessment of bleeding among trials.

The most common sites for anticoagulation-related bleeding are the nose, oral pharynx, and soft tissues, followed by the GI and urinary tracts. Hemarthrosis (bleeding into joint spaces) and retroperitoneal and intraocular bleeding represent less common hemorrhagic complications of anticoagulation therapy.[6] Gastrointestinal and urinary tract bleeding in anticoagulated patients is often caused by previously undiagnosed lesions. Menstrual blood flow may also be increased and prolonged in women taking anticoagulants. This problem may be clinically significant if there is an underlying pathologic condition (ovarian cysts, uterine fibroids, or polyps) resulting in abnormal vaginal bleeding.

For VTE treatment, the DOACs rivaroxaban and apixaban both showed significantly lower rates for major bleeding in clinical trials compared to warfarin, whereas edoxaban and dabigatran showed comparable rates. A recent meta-analysis demonstrated no statistically significant differences for efficacy and safety associated with most treatment strategies used to treat acute VTE compared with the LMWH/VKA combination.[88] However, it showed that the UFH/VKA combination is associated with a higher rate of recurrent VTE and that rivaroxaban and apixaban demonstrated a lower risk for major bleeding.

Although it is uncommon, intracranial bleeding resulting in hemorrhagic stroke represents the most common cause of fatal bleeding associated with warfarin therapy. Rates of intracranial hemorrhage associated with anticoagulants have been estimated to range from 0.3% to 2%, and up to 60% are fatal.[6] The DOACs have been shown to be as effective as warfarin for stroke prevention in patients with atrial fibrillation and are associated with lower rates of intracranial hemorrhage and reduced all-cause mortality. However, all of the DOACs, except for apixaban, are associated with a 25% increased risk of gastrointestinal bleeding.[89]

Many factors influence the risk of hemorrhagic complications associated with warfarin. The frequency of bleeding is higher in the first 3 months of therapy than during subsequent months.[90] Unlike heparin, the intensity of anticoagulation with warfarin directly influences the risk of bleeding, including intracranial hemorrhage.[91] Other patient-specific variables that influence the risk of warfarin-associated bleeding include a history of GI bleeding, serious comorbid disease (including malignancy), and concomitant therapy with aspirin, clopidogrel, or nonsteroidal anti-inflammatory drugs (NSAIDs).[6]

Several bleeding risk scores are available, including HAS-BLED (Hypertension, Abnormal renal or liver function, Stroke, Bleeding, Labile INR, Elderly, Drugs and alcohol) and ATRIA (Anticoagulation and Risk Factors in Atrial Fibrillation), which may identify patients at higher risk of bleeding; however, how best to use these tools remains in question.[92–94] None of these bleeding risk scores have been very effective at predicting risk for major or fatal bleeding in the first 3 months of anticoagulation for VTE, and none have performed well in the elderly in predicting major bleeding in the first 90 days of anticoagulation for VTE.[95–97]

Bleeding complications in A.W. can be minimized by careful attention to the signs and symptoms of bleeding by the patient and her caregivers, maintenance of the INR within the therapeutic range, avoidance of therapy with concomitant drugs known to increase the risk of bleeding or to increase the INR, and routine outpatient follow-up for INR monitoring and clinical assessment.

Skin Necrosis

Warfarin-induced skin necrosis is a rare but serious adverse effect of oral anticoagulation, occurring in approximately 0.01% to 0.1% of patients treated with warfarin.[98] Patients present within 3 to 6 days of the initiation of warfarin therapy with painful discoloration of the breast, buttocks, thigh, or penis. The lesions progress to frank necrosis with blackening and eschar. Skin necrosis appears to be the result of extensive microvascular thrombosis within subcutaneous fat and has been associated with hypercoagulable conditions, including protein C or protein S deficiency. In these patients, rapid depletion of protein C before depletion of vitamin K-dependent clotting factors during early warfarin therapy can result in an imbalance between procoagulant and anticoagulant activity, leading to initial hypercoagulability and thrombosis. Adequate use of injectable UFH, LMWH, or fondaparinux during initiation of warfarin can prevent the development of early hypercoagulability.

Warfarin therapy should be discontinued in patients who develop skin necrosis. However, subsequent warfarin therapy is not necessarily contraindicated if it is required for treatment or prevention of thromboembolic disease. In patients with protein C or protein S deficiency and a history of skin necrosis, warfarin therapy can be restarted at low dosages if given with UFH/LMWH/fondaparinux. Therapy is maintained until the INR has been within the therapeutic range for 72 hours. Supplementation of protein C through administration of fresh frozen plasma also may be indicated.

Purple Toe Syndrome

Purple toe syndrome is a rarely reported adverse effect that typically occurs 3 to 8 weeks after the initiation of warfarin therapy and is unrelated to intensity of anticoagulation.[99] Patients initially present with painful discoloration of the toes that blanches with pressure and fades with elevation. The pathophysiology of this syndrome has been related to cholesterol microembolization from atherosclerotic plaques, leading to arterial obstruction. Because cholesterol microembolization has been associated with renal failure and death, warfarin therapy should be discontinued in patients who develop purple toe syndrome.

Patient Education

CASE 11-6

QUESTION 1: E.N. is a 42-year-old man newly diagnosed with unprovoked DVT. He will be treated as an outpatient with enoxaparin 1.5 mg/kg SC daily and started on warfarin 5 mg PO daily using average daily dosing initiation. His primary care physician would like him to receive follow-up care in the medical center's pharmacist-managed anticoagulation clinic. What are the benefits of formal anticoagulation management services?

One of the keys to successful oral anticoagulant therapy is appropriate outpatient management. In comparison with routine medical care, management of warfarin therapy by anticoagulation

---

clinics is associated with significant reductions in bleeding and thromboembolic complications, with reductions in the rates of warfarin-related hospital admissions and ED visits, and with outcome-based cost savings for healthcare organizations.[100] Pharmacist-managed anticoagulation clinics offer many benefits for the management of anticoagulation therapy, including improved dosing regulation, continuous patient education, early identification of risk factors for adverse events, and timely intervention to avoid or minimize complications.[101] E.N.'s referral to a pharmacist-managed anticoagulation clinic is likely to improve his overall satisfaction with care and to improve his clinical outcomes.

The availability of portable INR self-testing devices also allows the option of anticoagulation monitoring in the home setting. Patient self-testing of INRs has been shown to result in comparable outcomes to high-quality anticoagulation delivered via anticoagulation clinics.[6] For patients that may prefer this monitoring method, a structured education and follow-up program should be designed and integrated with the patient's provider or the anticoagulation management service.

CASE 11-6, QUESTION 2: At his initial visit to the anticoagulation clinic, E.N. will receive extensive education about his warfarin therapy. What information should be conveyed to him by his anticoagulation provider to ensure the safety and efficacy of warfarin therapy?

Successful warfarin therapy depends on the active participation of knowledgeable patients.[6] The anticoagulant effect of warfarin is influenced by various factors, and fluctuations in the intensity of the anticoagulant effect of warfarin can increase the risk of both hemorrhagic complications and recurrent thromboembolism. Pharmacists and other providers can improve adherence to the medication schedule, as well as ensure the safety and efficacy of warfarin therapy, by providing appropriate education to patients treated with this agent.

Key elements that form the basis of a thorough patient education program for anticoagulation therapy are listed in Table 11-20. This information may be conveyed through written teaching materials, recorded instruction, individual or group discussion, or a combination of these approaches. Many useful educational tools are available from the manufacturers of the oral anticoagulants and from other noncommercial sources.

E.N. should receive extensive education about warfarin therapy in an individual teaching session or an organized education program. A wallet card, medical bracelet, or alternative method of identifying him as a patient treated with warfarin should be provided. The healthcare provider who assumes responsibility for his outpatient warfarin therapy will need to provide continuing reinforcement of the essential elements of medication information at each follow-up visit.

Factors that Influence Warfarin Dosing

CASE 11-6, QUESTION 3: After receiving 6 days of enoxaparin therapy and six doses of warfarin 5 mg/day PO, E.N.'s INR is 2.4. Enoxaparin is discontinued and E.N. is instructed to continue his current dosage of warfarin. He is scheduled to return to the anticoagulation clinic in 1 week for re-evaluation. At that time, his INR is 1.7. What factors might account for this change in the intensity of anticoagulation?

Patients should always be questioned about their understanding of the prescribed dose and their adherence to the prescribed regimen. Questions might include, "What dose of the medication have you been taking?" "What time of the day do you take your medication?" and "How many times in the last week did you miss a dose of your medication?" If there is no evidence of misunderstanding of the correct dose or of noncompliance, numerous other factors should be considered that are known to influence warfarin dosing requirements in individual patients during both initiation and maintenance phases of therapy. Changes in dietary vitamin K intake, underlying disease states and clinical condition, alcohol ingestion, genetic factors, and concurrent medications can significantly change the intensity of therapy, resulting in the need for dosing adjustments to maintain the INR within the therapeutic range. In a dosing cohort of 1,015 patients on warfarin therapy, body surface area, age, target INR, amiodarone use, smoker status, race, current thrombosis, VKORC1 polymorphism 1639/3673 G.A, CYP2C9(*)3, and CYP2C9(*)2 were all independent predictors of warfarin therapeutic dose.[102]

Table 11-20

Key Elements of Patient Education Regarding Oral Anticoagulation

Identification of generic and brand names
Purpose of therapy
Expected duration of therapy
Dosing and administration
Visual recognition of drug and tablet strength
What to do if a dose is missed

Recognition of signs and symptoms of bleeding
Recognition of signs and symptoms of thromboembolism
What to do if bleeding or thromboembolism occurs
Potential for interactions with prescription and over-the-counter medications and natural/herbal products
Limiting use of alcohol
Avoidance of pregnancy
Significance of informing other healthcare providers that patient is taking anticoagulation, and when notify anticoagulation provider when invasive procedures are being scheduled
When, where, and with whom follow-up will be provided
Dabigatran only: swallow whole, keep in original container, caution about potential for GI upset
Rivaroxaban only: take with food (evening meal)
Warfarin only: importance of INR monitoring and expected frequency, consistency of vitamin K

INR, international normalized ratio.

Dietary Vitamin K Intake

The two primary sources of vitamin K in humans are the biosynthesis of vitamin K_2 (menaquinone) by intestinal bacteria and dietary intake of vitamin K_1 (phytonadione). The US-recommended daily allowance for vitamin K is 70 to 140 mcg/day, and the typical Western diet provides approximately 300 to 500 mcg/day.[103] Vitamin K is found in high concentrations in certain foods, including green leafy vegetables (asparagus, broccoli, Brussels sprouts, cabbage, cauliflower, collard greens, endive, kale, lettuce, parsley, spinach, and turnip greens), soy milk, certain oils, certain nutritional supplements, and multiple vitamin products.

Variations in vitamin K intake have been linked to INR fluctuations in patients taking warfarin.[104,105] In addition, diets high in vitamin K content have been associated with acquired warfarin resistance, defined as excessive warfarin dosing requirements to reach a therapeutic INR range.[106] Numerous cases have also been reported in which patients previously stabilized with warfarin experienced elevations in INR with or without hemorrhagic complications when dietary sources of vitamin K were eliminated. Conversely, reductions in INR with or without thromboembolic complications have been reported in patients in whom dietary sources of vitamin K have been added.

Table 11-21

Warfarin Interactions with Disease States and Clinical Conditions

Clinical Condition	Effect on Warfarin Therapy
Advanced age	Increased sensitivity to warfarin due to reduced vitamin K stores and/or lower plasma concentrations of vitamin K-dependent clotting factors

Pregnancy	Teratogenic; avoid exposure during pregnancy
Lactation	Not excreted in breast milk; can be used postpartum by nursing mothers
Alcohol use	▪ Acute ingestion: inhibits warfarin metabolism, with acute elevation in INR ▪ Chronic ingestion: induces warfarin metabolism, with higher dose requirements
Liver disease	▪ May induce coagulopathy by decreased production of clotting factors, with baseline elevation in INR ▪ May reduce clearance of warfarin
Kidney disease	Reduced activity of CYP2C9, with lower warfarin dose requirements
Heart failure	Reduced warfarin metabolism due to hepatic congestion
Nutritional status	Changes in dietary vitamin K alter response to warfarin
Tube feedings	Decreased sensitivity to warfarin, possibly caused by changes in absorption or vitamin K content of nutritional supplements
Smoking and tobacco use	▪ Smoking: may induce CYP1A2, increasing warfarin dosing requirements. ▪ Chewing tobacco: may contain vitamin K, increasing warfarin dosing requirements
Fever	Increased catabolism of clotting factors, causing acute increase in INR
Diarrhea	Reduction in secretion of vitamin K by gut flora, causing acute increase in INR
Acute infection/inflammation	Increased sensitivity to warfarin

INR, international normalized ratio.

This data illustrate the potential clinical significance of dietary changes in patients taking warfarin. To minimize these potential effects, E.N. should be counseled to maintain a consistent intake of dietary vitamin K.[107] His final warfarin maintenance dose will be partially influenced by his typical diet. However, restriction of dietary vitamin K intake is unnecessary, except in cases of significant resistance to the anticoagulant effect of warfarin. E.N. should be aware of the types of foods and supplements that contain large quantities of vitamin K, and should be counseled to maintain a consistent diet, to avoid bingeing with foods high in vitamin K content, and to report significant dietary changes to his healthcare provider. Appropriate assessment and follow-up are essential to prevent hemorrhagic or thromboembolic complications that may arise from changes in INR resulting from dietary alterations.

Underlying Disease States and Clinical Conditions

The presence or exacerbation of various medical conditions can also influence anticoagulation status[71] (Table 11-21). Diarrhea-associated alterations in intestinal flora can reduce vitamin K absorption, resulting in elevations in INR. Fever enhances the catabolism of clotting factors and can increase INR. Heart failure, hepatic congestion, and liver disease can also cause significant elevations in INR because of a reduction in warfarin metabolism. End-stage renal disease is associated with decreased CYP2C9 activity, resulting in lower warfarin dose requirements.

The impact of changes in thyroid function on warfarin dose requirements is controversial.[108] It has been suggested that levothyroxine initiation accelerates clotting factor catabolism, enhancing warfarin’s anticoagulation effect; however, there is conflicting evidence in whether a warfarin–levothyroxine interaction has an impact on the INR.[109,110] A recent retrospective review did not show a difference in the mean warfarin dose/INR ratios before and after levothyroxine initiation, suggesting that no clinical interaction exists, and additional monitoring may not be necessary.[111]

Acute physical or psychologic stress has been reported to increase INR. Increased physical activity has also been reported to increase the warfarin dosing requirement. Smoking can induce CYP1A2, which may increase warfarin metabolism in certain patients, resulting in increased dose requirements.[112] Due to its high vitamin K content, chewing smokeless tobacco can suppress the INR response.[113]

Thorough education of patients taking warfarin should include detailed attention to recognizing the signs and symptoms of changes in underlying disease states and clinical conditions that can influence warfarin dosing requirements. They should be instructed to contact their anticoagulation management program whenever changes occur that might influence INR and warfarin dose requirement.

Alcohol Ingestion

Chronic alcohol ingestion has been associated with induction of the hepatic enzyme systems that metabolize warfarin. Therefore, warfarin dosing requirements are sometimes higher in alcoholic patients. Conversely, acute ingestion of large amounts of alcohol can slow warfarin metabolism through competitive inhibition of metabolizing enzymes, leading to elevations in INR and an increased risk of bleeding complications.[6,107] Despite some reports linking low amounts of alcohol to an elevated INR,[114] in general it is believed that moderate intake of alcoholic beverages is not associated with alterations in the metabolism or the therapeutic effect of warfarin as measured by INR. Patients taking warfarin should be educated to limit their alcohol consumption to less than one to two alcoholic beverages per day. Chronic drinkers should be counseled to limit their drinking and maintain a regular pattern to avoid fluctuations in INR.[107] E.N. does not need to abstain from drinking alcoholic beverages in moderation, but he should be counseled to avoid the sporadic ingestion of large amounts of alcohol.

Conversely, alcoholic liver disease (i.e., cirrhosis) can alter multiple hemostatic mechanisms and reduces production of hepatic clotting factors. Decreased production and clearance of vitamin K-dependent clotting factors accounts for the prolonged PT and INR often seen in these patients. Therefore, an increased response to warfarin would be expected in patients with liver impairment. Worsening liver function is also a predictor for bleeding complications and patients with end-stage liver disease are at increased risk of bleeding. Before instituting warfarin therapy in these patients, the risks of bleeding associated with both the underlying liver disease and warfarin therapy must be weighed against the benefit of preventing thromboembolic events. If warfarin is indicated, the best approach would be to use a cautious initiation and dose titration approach by starting with lower doses and titrating up slowly to goal. Small increases in dosage should be made, if indicated, recognizing that the full effect of any dose adjustment may be delayed in patients with severe liver dysfunction. Monitoring for bleeding complications is essential, even at goal INR ranges, when warfarin is used in patients with liver dysfunction.

Genetic Factors

The cytochrome P450 (CYP) 2C9 and vitamin K epoxide reductase complex 1 (VKORC1) genotypes have been associated with warfarin dose requirements, and dosing algorithms incorporating genetic and clinical information have been shown to be predictive of stable warfarin dose.[115] However, dosing algorithms that incorporate CYP2C9 genotype and vitamin K epoxide reductase complex 1 (VKORC1) haplotype along with other patient characteristics to predict warfarin maintenance doses showed mixed results in randomized, prospective clinical trials, questioning the utility of this approach.[116,117] Based on current data failing to show a benefit, ACCP recommends against the routine use of pharmacogenetic testing for guiding doses of VKA (Grade 1B).[21] Further research is needed to determine the place of warfarin pharmacogenetic testing.

CASE 11-6, QUESTION 4: How should E.N. be assessed and evaluated at this clinic appointment?

At each clinic visit, E.N. should be assessed for signs and symptoms of bleeding, and for signs and symptoms of clot progression and/or recurrence. The accuracy and reliability of the INR test should be also considered. Additionally, E.N. should be asked about missed or extra doses of warfarin, dietary changes (increases or decreases in vitamin K, alcohol use), medication changes, recent illnesses (such as nausea/vomiting/fever/chills/diarrhea), any recent falls, and any known upcoming procedures. Regardless of the INR result, all factors that may influence E.N.'s anticoagulation status should be evaluated carefully.

Dosing Adjustments

CASE 11-6, QUESTION 5: After a thorough assessment, it is determined that E.N. has adhered to his prescribed warfarin dosage schedule and that there is no apparent explanation to account for his reduction in INR. How should his warfarin dosage be adjusted?

When overanticoagulation or underanticoagulation is verified, an adjustment in warfarin dosing may be necessary. Table 11-22 describes approaches to warfarin dosing adjustments for maintenance therapy. Typically, dosing adjustments of 5% to

20% of the total daily dose (or the total weekly dose) are appropriate to reach the therapeutic range.[118] Because warfarin does not follow linear kinetics, small adjustments in dose can lead to large INR changes, and thus large dose adjustments (i.e., greater than a 20% increase or decrease of the total weekly dose) are not recommended. These maintenance dosing guidelines should only be applied to patients who have reached a steady state dose and not in the initiation phase of therapy.

Because E.N. is currently taking 5 mg daily, an adjustment of 15% would increase his dosage to approximately 5.5 mg/day. This dosing adjustment can be made by having him take one 5-mg tablet and half of a 1-mg tablet each day (same daily dosing) or by having him take 7.5 mg 2 days per week and 5 mg all other days of the week (alternate-day dosing). Patient preference about breaking tablets in half, the likelihood of confusion about different tablet sizes, and potential confusion on taking different doses on different days of the week should be the primary considerations when selecting a dosing method.[119]

Table 11-22

Warfarin Dose Adjustment Nomogram for Maintenance Therapy

INR (Goal 2–3)	Suggested change in total "weekly" dose
<1.5	Give extra one-time daily dose and increase weekly dose by 10%–20%
1.5–1.9	Increase weekly dose by 5%–15% (may give extra one-time daily dose)[a]
2.0–3.0	Maintain current dose
3.1–4.0[b]	Hold up to one daily dose and decrease weekly dose by 5%–20%[a]
4.1–5.0[b]	Hold up to two daily doses and decrease weekly dose by 10%–20%[a]

Warfarin Use in Adults: Clinical Care Guideline, University of Illinois Hospital and Health Sciences System.

[a] If transient cause identified, may need not to increase/decrease weekly dose.

[b] Assumes no active bleeding.

Frequency of Follow-Up

CASE 11-6, QUESTION 6: E.N. agrees to increase his warfarin dosage to 5.5 mg/day. A new prescription for 1-mg tablets is written for him, and he is instructed about the use of these tablets. When should his INR be reassessed and his anticoagulation status, including physical assessment, be re-evaluated?

It will take several days for his INR to reach a new steady state because of the long elimination half-lives of both warfarin and the vitamin K-dependent clotting factors. His INR should be rechecked approximately 1 week after a dosing adjustment has been made. Once a stable dose has been reached, patient assessment and INR monitoring typically occurs every 4 to 6 weeks. However, if E.N. displays any signs of medical instability or nonadherence, a follow-up schedule of every 1 to 2 weeks is indicated (Table 11-23). For carefully selected patients with well-controlled INRs, recall frequencies out to 12 weeks can be recommended.[21] For patients taking warfarin with previously stable therapeutic INRs who present with a single out-of-range INR of ≤ 0.5 below or above therapeutic, continuing the current dose and testing the INR within 1 to 2 weeks is suggested, rather than changing the overall daily dose.[21]

Management of Overanticoagulation

CASE 11-7

QUESTION 1: V.G., who has been taking warfarin for 3 years with good INR control, noted bright red blood after a bowel movement (hematochezia) that resolved and has not returned. In the ED, an INR of 5.6 was reported. Her Hct and Hgb were both within normal limits, as were her vital signs. A stool guaiac test was positive, and multiple external hemorrhoids were detected. How should this adverse effect of warfarin be treated in V.G.?

Management of overanticoagulation depends on the clinical presentation of the patient. In the case of an elevated INR without bleeding complications, interruption of warfarin therapy by holding one or two doses until the INR returns to the therapeutic range is usually sufficient.[21] Minor bleeding complications accompanied by an elevated INR can also be managed by withholding warfarin therapy for a short period until bleeding resolves. In either case, the patient should be questioned to determine a possible cause for overanticoagulation, including intake of extra doses of warfarin, changes in diet or alcohol intake, changes in underlying medical conditions, or the use of other medications. In some cases, no apparent explanation is identified. Depending on the cause, a reduction in the maintenance dosing of warfarin may be necessary.

Table 11-23

Frequency of International Normalized Ratio Monitoring and Patient Assessment during Warfarin Therapy

Initiation Therapy	
Inpatient initiation	Daily
Outpatient flexible initiation method	Daily through day 4, then within 3–5 days
Outpatient average daily dosing method	Within 3–5 days, then within 1 week
After hospital discharge	Within 3–5 days
First month of therapy	Every 1–4 days until therapeutic, then weekly
Maintenance Therapy	

Medically stable inpatients	Every 1–3 days
Medically unstable inpatients	Daily
After hospital discharge	If stable, within 3–5 days; If unstable, within 1–3 days
Routine follow-up in medically stable and reliable patients	Every 4–12 weeks
Routine follow-up in medically unstable or unreliable patients	Every 1–2 weeks
Dose held today for significant over-anticoagulation	In 1–2 days
Dosage change today	Within 1–2 weeks
Dosage change <2 weeks ago	Within 2–4 weeks

The time required for INR to return to the therapeutic range after warfarin is withheld depends on several patient characteristics. Advanced age, lower warfarin maintenance dose requirements, and higher INR are associated with increased time for INR correction.[120] Other factors that can prolong the time for INR to return to the therapeutic range include decompensated heart failure, active malignancy, and recent use of medications known to potentiate warfarin.

Although previously recommended and commonly used, low-dose vitamin K in patients with elevated INR 4.5 to 10 and not bleeding is not associated with a reduction in major bleeding, and is no longer routinely recommended.[21] However, patients with INRs greater than 10 and not bleeding may benefit from small doses of oral vitamin K 1 to 2.5 mg. The decision on whether to give vitamin K in nonbleeding patients needs to consider the patient's individual risk for bleeding and thrombosis.[21] An oral dose of 1 to 2.5 mg can correct overanticoagulation in 24 to 48 hours without causing prolonged resistance to warfarin therapy, a problem commonly seen with larger (10 mg) doses of vitamin K. Intramuscular administration is contraindicated due to the risk of hematoma formation, and SC administration of vitamin K is not recommended because of variable absorption.[121]

IV doses of 0.5 to 1 mg of vitamin K can correct overanticoagulation within 24 hours.[6] This approach is also useful for reversal of therapeutic anticoagulation before invasive procedures and can be used to correct overanticoagulation in high-risk cases. Intravenous vitamin K should be diluted in a minimum of 50 mL intravenous fluid and administered with an infusion pump over a minimum of 20 minutes to prevent flushing, hypotension, and cardiovascular collapse.[6] Although these symptoms resemble anaphylaxis, the mechanism of this adverse response is unclear: It is not known whether it is caused by phytonadione or by the vehicle in which phytonadione is formulated. If this adverse reaction occurs, administration of epinephrine may be indicated, as well as other standard measures to support blood pressure and maintain the airway.

Rapid reversal of warfarin therapy is indicated in the setting of major, life-threatening bleeding (i.e., severe gastrointestinal bleeding, intracranial hemorrhage). Fresh frozen plasma or factor concentrates to replace clotting factors will decrease the INR for 4 to 6 hours and should be administered as needed with careful monitoring of volume status.[21] Supplementation with high-dose IV vitamin K (10 mg) may also be indicated. Administration of IV vitamin K will reverse the effects of warfarin within 6 to 12 hours. However, if continued warfarin therapy is indicated when bleeding resolves, anticoagulation with heparin may be necessary for as long as 7 to 14 days until the effect of high-dose vitamin K is diminished and warfarin responsiveness returns.

Hematochezia may be an early sign of more serious bleeding, but in many cases this condition is associated with minor bleeding episodes and identifiable causes such as hemorrhoids. In a reliable patient, holding the warfarin until the INR returns to a therapeutic level usually suffices, along with the addition of a bowel regimen to prevent straining with bowel movements, topical cream to minimize swelling and irritation, increased fluids, and/or increased fiber intake. Because V.G. appears to have only minor bleeding from the stool, is hemodynamically stable, and has a stable hemoglobin, withholding warfarin is appropriate. If the patient has never had a colonoscopy, then evaluation for the appropriateness of this test may be warranted.

Use in Pregnancy

CASE 11-8

QUESTION 1: M.P., a 25-year-old woman, takes warfarin for chronic therapy for recurrent DVTs. She tells you today that she missed her menses and thinks she may be pregnant. A pregnancy test ordered today was positive. What effects might warfarin have on the fetus? Are UFH or LMWHs safer alternatives in this situation?

Warfarin and other coumarin anticoagulants cross the placental barrier and may place the fetus at risk for hemorrhage and teratogenic effects.[122] Up to 30% of pregnancies that involve exposure to coumarin result in abnormal liveborn infants, and up to 30% in spontaneous abortion or stillbirth. Congenital abnormalities such as stippled calcifications and nasal cartilage hypoplasia primarily occurred in infants born to mothers receiving warfarin during the first trimester of pregnancy, with the highest risk during weeks 6 to 12. Other abnormalities, involving the central nervous system and eyes, are more likely to occur when the mother is taking warfarin later in the pregnancy. In addition, because warfarin crosses the placenta, fatal bleeding complications may occur.

Women of childbearing age who require anticoagulation should be counseled about options for contraception. Patients who become pregnant while receiving warfarin should be informed of the risks of continued anticoagulation to the fetus, as well as the risk to themselves of discontinuing anticoagulation.

Other options for pregnant women who require anticoagulation include UFH and LMWHs.[122] Because these agents do not cross the placenta, they are preferred over warfarin for use in pregnancy. Many clinical trials have validated the safety and efficacy of UFH and LMWHs in the prevention and treatment of DVT and PE during pregnancy, with LMWH generally preferred to UFH for long-term management throughout pregnancy.[122,123] When used at full doses for the treatment of VTE during pregnancy, dosing must be adjusted throughout the pregnancy to account for the expected increase in the body weight of the mother and the reported increase in clearance of LMWH during pregnancy.[124,125] Selected current recommendations for use of anticoagulants in pregnancy are outlined in Table 11-24.

After being informed of the risks associated with warfarin, M.P. decided to continue her pregnancy and to begin anticoagulation with LMWH. Because pregnant women were excluded from clinical trials with the DOACs due to their increased risk for maternal and fetal bleeding, their use in pregnancy is not recommended at this time. Warfarin therapy should be discontinued immediately and LMWH initiated using SC treatment doses as previously described. Dosing adjustments may be required throughout pregnancy based on changes in body weight and clearance, possibly guided by anti-factor Xa monitoring. Potential adverse effects of LMWH use, including hemorrhage, thrombocytopenia, and osteoporosis, should be monitored appropriately.

For women desiring spinal anesthesia during delivery, treatment doses of LMWH should be discontinued a minimum of 24 hours before induction of labor, cesarean section, or placement of an epidural catheter, and restarted no sooner than 24 hours postoperatively, and with adequate hemostasis in place.[126] Neuraxial anesthesia should not be used in anticoagulated women (i.e., within 24 hours of the last treatment dose of LMWH, or for patients receiving IV UFH that have prolonged aPTTs). In patients not receiving epidural catheters, postpartum anticoagulation may be started 12 to 24 hours after delivery as long as there are no bleeding concerns.[126] Consider IV UFH in women at high risk of bleeding, with LMWH reasonable for most women. Restart warfarin when hemostasis has occurred, bridging with UFH or LMWH until the INR is therapeutic. Warfarin, LMWH, and UFH do not accumulate in breast milk and do not induce anticoagulant effect in the infant and may be used in women who breastfeed[122]; therefore, M.P. can safely breastfeed. The DOACs are not currently recommended during breastfeeding.[122,123]

Table 11-24

Selected Recommendations for Anticoagulation during Pregnancy

Clinical Situation	Antepartum Options	Postpartum
1. Prophylaxis: Prior VTE		
Low risk of recurrent VTE (single episode of VTE associated with	Clinical vigilance	Prophylactic or intermediate dose LMWH or VKA (INR 2–3) for 6

transient RF not related to pregnancy or use of estrogen)		weeks over no prophylaxis
Moderate/high risk of recurrent VTE (single unprovoked VTE, pregnancy- or estrogen-related VTE, or multiple prior unprovoked VTE not receiving long-term AC)	Prophylactic or intermediate dose LMWH over clinical vigilance or routine care	Prophylactic or intermediate dose LMWH or VKA (INR 2–3) for 6 weeks over no prophylaxis
On long-term VKA	Adjusted-dose LMWH or 75% of a therapeutic dose of LMWH throughout pregnancy, over prophylactic dose LMWH	Resumption of long-term AC
2. Prophylaxis: No Prior VTE		
Homo-FVL or Prothrombin mutation and + FH for VTE	Prophylactic or intermediate dose LMWH	Prophylactic or intermediate dose LMWH or VKA (INR 2–3) for 6 weeks over no prophylaxis
All other thrombophilias who have + FH for VTE	Clinical vigilance	Prophylactic or intermediate dose LMWH or, in women who are not protein C or S deficient, VKA (INR 2–3) over routine care
Homo FVL or Prothrombin mutation and no positive FH for VTE	Clinical vigilance	Prophylactic or intermediate dose LMWH or VKA (INR 2–3) for 6 weeks over routine care
All other thrombophilias with no positive FH for VTE	Clinical vigilance	Clinical vigilance
Long-term oral anticoagulants for mechanical valve replacement	■ Adjusted-dose SC UFH ■ Adjusted-dose BID LMWH (adjusted to achieve manufacturer recommended 4-hour postdose peak anti-factor Xa concentration) ■ UFH or LMWH (as above) until the 13th week, with substitution by VKA until close to delivery when UFH or LMWH is resumed	Long-term warfarin to prior INR goal with UFH/LMWH overlap until INR above lower limit of therapeutic range

Adjusted-dose UFH: UFH SC q12h in doses adjusted to target a mid-interval aPTT into the therapeutic range.
Prophylactic LMWH: dalteparin 5,000 units SC q24h, tinzaparin 4,500 units SC q24h, or enoxaparin 40 mg SC q24h (At extremes of body weight modification of dose may be required).
Intermediate-dose LMWH: dalteparin 5,000 units SC q12h, enoxaparin 40 mg SC q12h.
Adjusted-dose LMWH: weight-adjusted, full treatment doses of LMWH, given once or twice daily: dalteparin 200 units/kg daily, tinzaparin 175 units/kg daily, dalteparin 100 units/kg q12h, or enoxaparin 1 mg/kg q12h.
AC: anticoagulation; BID, 2 times daily; FH, family history; FVL, factor V Leiden mutation; INR, international normalized ratio; LMWH, low-molecular-weight heparin; RF: risk factor; SC, subcutaneous; UFH, unfractionated heparin; VKA: vitamin K antagonist; VTE, venous thromboembolism.

PREVENTION OF CARDIOGENIC THROMBOEMBOLISM

Atrial Fibrillation

ANTICOAGULATION BEFORE CARDIOVERSION

CASE 11-9

QUESTION 1: T.S., a 66-year-old woman with hypertension and no other significant past medical history, presents to the cardiology clinic complaining of several days of fatigue and a "racing heart." On physical examination, her pulse is irregularly irregular, and her heart rate is approximately 120 beats/minute. Using ECG, a diagnosis of atrial fibrillation is made and cardioversion planned. Should T.S. be anticoagulated before cardioversion?

In atrial fibrillation, atrial activity and atrial enlargement cause stasis of blood within the atria and the left atrial appendage, which can result in atrial thrombus formation. Atrial thrombus formation increases the risk of systemic embolization; clinical manifestations include arterial embolization of the extremities or embolization of the splenic, renal, or abdominal arteries. However, the most prevalent site of embolization is the cerebral arterial system, resulting in transient ischemic attack or stroke with potentially devastating neurologic and functional impairment. Atrial fibrillation carries a fivefold risk of ischemic stroke without thromboprophylaxis.[127]

Both direct current cardioversion and pharmacologic cardioversion using antiarrhythmic drugs expose patients to an initial short-term increase in stroke risk from embolization secondary to resumption of normal atrial mechanical activity (see Chapter 15, Cardiac Arrhythmias). Data from a prospective cohort study of 437 patients noted a stroke incidence of 5.3% in patients with atrial fibrillation who were cardioverted without prior anticoagulation, but a significant reduction in stroke incidence to 0.8% was noted if patients who had received cardioversion were anticoagulated.[128] In addition to preventing the development of new atrial thrombi, anticoagulation allows any thrombus that may be present to endothelialize and adhere to the atrial wall so that the thromboembolic risk is minimized. Based on the assumed time course of thrombus development, as well as the presumed time course of clot endothelialization, patients who have been in atrial fibrillation for 48 hours or longer should receive 3 weeks of therapeutic anticoagulation with warfarin to a target INR of 2.5 (range, 2.0–3.0) before cardioversion is attempted.[127,129] Direct oral anticoagulants such as dabigatran, rivaroxaban, and apixaban are alternative options to warfarin therapy.[129] Despite a lower risk of stroke than that associated with atrial fibrillation, patients with atrial flutter should be treated similarly.

Whether T.S. has been in atrial fibrillation for 48 hours is not known; therefore, she requires a 3-week course of oral anticoagulation before cardioversion is attempted. If T.S. cannot tolerate her heart symptoms despite control of the ventricular response rate, her medical team might consider immediate cardioversion without anticoagulation if transesophageal echocardiography (TEE) is used to rule out left atrial thrombi. TEE is much more sensitive than transthoracic echocardiography (TTE) to visualize the left atrium and the left atrial appendage.

In a clinical trial, 1,222 patients with atrial fibrillation for a duration of 2 days or more were randomly assigned to either cardioversion guided by TEE or to conventional anticoagulation prior to cardioversion.[130] Patients assigned to conventional treatment and patients in the TEE group in whom thrombus was detected received a 3-week course of warfarin before cardioversion. Patients without detectable thrombus by TEE were cardioverted without prior anticoagulation. All patients received 4 weeks of postcardioversion anticoagulation. Thromboembolic rates were identical between patients who received conventional treatment and those whose treatment was guided by TEE (0.5% vs. 0.8%, $p = 0.5$).[130]

ANTICOAGULATION AFTER CARDIOVERSION

CASE 11-9, QUESTION 2: After 3 weeks of regular intensity warfarin therapy, T.S. is successfully cardioverted to normal sinus rhythm. Should anticoagulation be discontinued?

Despite normalization of atrial electrical activity, restoration of effective atrial mechanical activity after cardioversion of atrial fibrillation can be delayed for up to 3 weeks. In addition, many patients who are cardioverted successfully will revert to atrial fibrillation during the first month. These factors contribute to the recognized delay in stroke presentation after cardioversion in patients with atrial fibrillation. Therefore, anticoagulation should be continued after cardioversion for a minimum 4 weeks. Longer duration of anticoagulation therapy should be based on the individual patient's thromboembolic risk profile.[127,129]

ANTICOAGULATION FOR PAROXYSMAL, PERMANENT, OR PERSISTENT ATRIAL FibRILLATION

CASE 11-9, QUESTION 3: Two weeks after successful cardioversion, T.S. presents to the ED with chest palpitations and light-headedness. An ECG is performed and indicates atrial fibrillation again. What decisions regarding anticoagulation need to be made?

Anticoagulation in Valvular Atrial Fibrillation

Atrial fibrillation secondary to valvular heart disease has historically been recognized as a significant risk factor for stroke. Patients with atrial fibrillation who have a history of rheumatic mitral valve disease have a 17-fold higher incidence of stroke than in matched controls. Patients with valvular atrial fibrillation require long-term, regular intensity anticoagulation with warfarin to a target INR of 2.5 (range, 2.0–3.0) to prevent thromboembolism and stroke. DOACs have not been studied in this patient population and should be avoided at this time.[127,129]

Anticoagulation in Nonvalvular Atrial Fibrillation

Nonvalvular heart disease is the most common cause of atrial fibrillation and, like valvular heart disease, represents a significant risk for stroke in patients with atrial fibrillation. Five clinical trials have substantiated the role of warfarin in the primary prevention of systemic embolization and stroke in chronic, nonvalvular atrial fibrillation.[127,129,131] All five trials compared warfarin with a placebo and were terminated before completion because of the substantial benefit of warfarin. In comparison with a placebo, warfarin significantly reduced the risk of stroke from approximately 5% per year to approximately 2% per year, with an average relative risk reduction of 67%. Based on the results of these trials, long-term anticoagulation with warfarin to a goal INR of 2.5 (range, 2.0–3.0) is recommended in patients like T.S., who have atrial fibrillation secondary to nonvalvular heart disease.[127,129,131]

Several clinical trials have attempted to define the comparative efficacy of warfarin versus aspirin in the prevention of stroke associated with atrial fibrillation.[127,129,132] Compared with a placebo or control, aspirin decreases the risk of stroke in patients with atrial fibrillation. However, that reduction is not as substantial as the reduction seen with warfarin. In clinical trials comparing warfarin and aspirin, the risk reduction associated with warfarin is significantly larger than that of aspirin. However, aspirin may be appropriate in certain patients at low risk for stroke associated with atrial fibrillation based on individualized risk assessment using the CHADS$_2$ and CHA$_2$ DS$_2$-VASc score (Table 11-9). The CHADS$_2$ score is currently endorsed by ACCP whereas the CHA$_2$DS$_2$VASc score is endorsed by the American Heart Association/American College of Cardiology/Heart Rhythm Society (AHA/ACC/HRS) and the European Society of Cardiology (ESC) (see Chapter 15, Cardiac Arrhythmias).

Subsequent trials have confirmed the superiority of warfarin over the combination of aspirin plus clopidogrel for stroke prevention in atrial fibrillation, and the increased risk of intracranial hemorrhage when aspirin and clopidogrel are combined.[133,134]

Direct Oral Anticoagulants

The direct thrombin inhibitor (dabigatran) and direct factor Xa inhibitors (rivaroxaban, apixaban, and edoxaban) have all been compared to warfarin for stroke prevention in patients with nonvalvular atrial fibrillation.[135–138]

Patient-specific characteristics such as age, renal function, weight, concomitant medications, and past medical history should be considered when selecting the most appropriate anticoagulant for initial therapy. Cost, insurance coverage and patient preference with regard to number of daily doses, frequency of monitoring, etc. must also be taken into account[139] (see Chapter 15, Cardiac Arrhythmias).

The decision to continue long-term anticoagulation with warfarin in T.S. should be based on an evaluation of the likelihood that her atrial fibrillation will become chronic with a paroxysmal, persistent, or permanent presentation, as well as an assessment of her risk of stroke compared with her risk of anticoagulant-associated bleeding complications. Because of her age and history of hypertension ($CHADS_2$ score of 2 and CHA_2DS_2-VASc score of 3), the appropriate strategy should be long-term anticoagulation, either with warfarin at a goal INR of 2.5 (range, 2.0–3.0) or full-dose DOAC therapy.

Cardiac Valve Replacement

MECHANICAL PROSTHETIC VALVES

CASE 11-10

QUESTION 1: P.B., a 59-year-old woman with a history of rheumatic mitral valve disease, has undergone mitral valve replacement. A St. Jude (bileaflet mechanical) valve has been implanted, and heparin therapy is initiated postoperatively. Does P.B. require continued anticoagulation with warfarin?

Mechanical prosthetic valves confer a significant thromboembolic risk by providing a foreign surface in contact with blood components on which platelet aggregation and thrombus formation can occur. Valvular thrombosis can impair the integrity of valve function and can lead to embolization with systemic manifestations, including stroke.[140] The incidence of thromboembolic complications depends on the type of artificial valve (caged ball [Starr-Edwards] > tilting disk [Medtronic-Hall; Bjork-Shiley] > bileaflet [St. Jude]), as well as the anatomic position of the replacement (dual valve replacement > mitral > aortic).[141]

Long-term anticoagulation is required in patients with mechanical valve replacement because it significantly reduces the risk of stroke and other manifestations of systemic embolization (Table 11-9). Trials comparing different intensities of oral anticoagulation with warfarin in mechanical valve replacement helped identify the intensity of anticoagulation that protects against thromboembolic risk, while reducing the incidence of hemorrhagic complications.[142] Patients with a mechanical aortic valve replacement (AVR) (St. Jude bileaflet or tilting disc) in the aortic position should receive long-term anticoagulant therapy with warfarin to a target INR of 2.5 (range, 2.0–3.0).[140,143] For all other mechanical valve types in the aortic position, and for any mechanical mitral valve replacement (MVR), chronic warfarin therapy with a target INR of 3.0 (range, 2.5–3.5) is recommended. The concurrent use of low-dose aspirin (81 mg daily) is recommended for patients with mechanical mitral or aortic valve at low-bleeding risk.

In 2012, the RE-ALIGN trial was halted early after demonstrating a significant increase in thromboembolic events such as valve thrombosis, myocardial infarction, transient ischemic attack and stroke as well as significant increase in bleeding when taking dabigatran versus warfarin in patients with mechanical prosthetic valves.[144] Based on these results as well as case reports reporting valve thrombosis following transition from warfarin to dabigatran, the FDA issued a MedWatch safety alert recommendation that dabigatran should not be used in any patient with a mechanical heart valve. Subsequently, dabigatran's product information was also updated to include this contraindication. Based on the results of this trial, it is unlikely any other DOAC will be tested in the population; thus, all DOACs should not be used in patients with mechanical prosthetic valves. Therefore, P.B. would be required to continue warfarin indefinitely to reduce the risk of stroke and other systemic embolism.

BIOPROSTHETIC VALVES

CASE 11-11

QUESTION 1: E.F., an 82-year-old woman with a history of symptomatic aortic stenosis, has received a bioprosthetic (mammalian) aortic valve replacement. Is anticoagulant therapy required in E.F.?

Prosthetic heart valves extracted from mammalian sources (porcine or bovine xenografts, homografts) are significantly less thrombogenic than mechanical prosthetic valves. The period of greatest thromboembolic risk appears to be during the first 3 months after implantation. Therefore, anticoagulation with warfarin to an INR goal of 2.5 (range, 2.0–3.0) is recommended for 3 to 6 months following implantation of a bioprosthetic aortic or mitral valve in patients at low risk of bleeding (Table 11-9). After this period, long-term aspirin therapy (75–100 mg) is indicated.[140,143] Alternatively, treatment with only aspirin 75 to 100 mg daily is also reasonable in patients with a bioprosthetic aortic or mitral valve. More about E.F.'s bleeding risk would need to be determined, however due to her age, long-term aspirin therapy only may be reasonable.[140] Transcatheter aortic valve replacement (TAVR) is a new technique that avoids the open chest approach. Initially, clopidogrel 75 mg daily for the first 3 to 6 months, followed by long-term aspirin was recommended following TAVR. However, the most recent AHA/ACC guidelines recommend either warfarin with a goal INR of 2.5 (range, 2.0–3.0) for at least 3 months or clopidogrel 75 mg daily for the first 6 months following TAVR in addition to life-long aspirin 75 to 100 mg daily.[143]

BRIDGE THERAPY

Management of Anticoagulation Around Invasive Procedures

CASE 11-12

QUESTION 1: L.P. is a 48-year-old woman with a history of valvular heart disease and a St. Jude mitral valve replacement. She is adequately anticoagulated with warfarin 7.5 mg once daily to a goal INR range of 2.5 to 3.5. Recently, she has complained of episodic rectal bleeding and is scheduled for a colonoscopy in several weeks. Her gastroenterologist calls the anticoagulation clinic to determine the most appropriate plan for reversal of her warfarin before the procedure. What are the options?

When an invasive procedure is planned, it is often necessary to reverse the effects of warfarin to minimize the risk of bleeding complications associated with the procedure, which can be worsened by the presence of an anticoagulant. It can take several days for the anticoagulant effect of warfarin to be reversed after discontinuation of the drug, but in that period of time, a patient may be at risk for thromboembolic complications associated with underanticoagulation. Bridge therapy is the term that refers to the use of a relatively short-acting injectable anticoagulant (UFH, LMWH) as a substitute for warfarin before and immediately after an invasive procedure to shorten the period of time a patient is without any anticoagulation.[145] Because UFH and LMWH have shorter elimination half-lives than warfarin, they can be stopped just before the invasive procedure without increasing the risk of bleeding associated with the procedure. The last dose of LMWH and SC UFH should be given at least 24 hours before the scheduled procedure, whereas IV UFH infusions are discontinued 6 hours before the procedure. The timing of the last dose of LMWH may need to be extended based on a patient's renal function because it is renally eliminated. Because of their faster onsets of effect, these agents are resumed after invasive procedures once hemostasis is achieved to establish an immediate degree of anticoagulation. Resumption of therapeutic injectable anticoagulants after a high-bleeding risk surgery should be delayed until at least 48 to 72 hours postoperatively, whereas patients undergoing lower-bleeding risk procedures can be restarted 24 hours later. Warfarin is resumed simultaneously, and the bridging anticoagulant is continued until the INR reaches the therapeutic range.[145]

Current guidelines for bridging are based on the results of case series, observational studies, and nonrandomized trials involving patients with various indications for anticoagulation, including valve replacement. The decision to use bridging depends on the risk of bleeding associated with continued anticoagulation for the surgery or procedure to be performed and on the risk of thromboembolism associated with underanticoagulation in the patient in question. Recently, a large registry called The Outcomes Registry for Better Informed Treatment of Atrial Fibrillation (ORBIT-AF) included patients with atrial fibrillation that underwent temporary interruption of oral anticoagulation therapy and showed that bridging was associated with higher risk of bleeding and adverse events.[146] Shortly after, the interim results of the BRIDGE trial (Bridging Anticoagulation in Patients who Require Temporary Interruption of Warfarin Therapy for an Elective Invasive Procedure or Surgery) that randomized patients with atrial fibrillation to receive bridging therapy with LMWH or placebo showed similar findings to the ORBIT-AF registry. The study showed no difference in the rate of arterial thromboembolism between the bridging and nonbridging group; however, the bridging group showed significantly higher rates of major bleeding. The mean $CHADS_2$ score was 2.3 and patients with mechanical heart valve or stroke, systemic embolism, and transient ischemic attack within the previous 12 weeks were excluded from the trial. Major surgical procedures associated with high rates of arterial thromboembolism and bleeding were also underrepresented. Therefore, the results from the BRIDGE trial should not be applied to patients that were underrepresented.[147]

Individualized risk assessment and bridge therapy planning are necessary for each patient who may require temporary discontinuation of warfarin. Current recommendations for risk stratification are outlined in Table 11-25. High-risk and moderate-risk patients typically receive bridge therapy if warfarin needs to be withheld, whereas in low-risk patients, warfarin is simply withheld before the invasive procedure, without the need for bridging. The bleeding risk of a performed procedure or surgery must also be weighed. Efforts should be made to continue oral anticoagulation in a patient with high thromboembolic risk undergoing a procedure with low-bleeding risk, such as a dental extraction or cataract surgery. Table 11-26 includes examples of high- versus low-bleeding risk surgeries.

Clinical outcomes in patients bridged with LMWH or UFH are similar and overall costs are lower for LMWH because of the avoidance of hospital admission for IV UFH administration; therefore, the use of LMWH is recommended whenever possible.[145] UFH may be preferred in patients with significant renal impairment (CrCl < 30 mL/minute), and if LMWHs are used, reduced doses are suggested.[21] Monitoring anti-Xa levels for accumulation may be prudent if patients require a prolonged course of therapy (over 7 days). A guideline for bridge therapy based on the risk of thromboembolism and on renal function is presented in Table 11-27.

Table 11-25

Risk Stratification for Determining the Need for Bridge Therapy

	Indication for VKA Therapy		
Risk Stratum	**Mechanical Heart Valve**	**Atrial Fibrillation**	**Venous Thromboembolism**
High	■ Any mitral valve prosthesis ■ Older (caged-ball or tilting disk) aortic valve prosthesis ■ Recent (within 6 months) stroke or transient ischemic attack	■ $CHADS_2$ score of 5 or 6 ■ Recent (within 3 months) stroke or transient ischemic attack ■ Rheumatic valvular heart disease	■ Recent (within 3 months) VTE ■ Severe thrombophilia (e.g., deficiency of protein C, protein S or antithrombin, antiphospholipid antibodies, or multiple abnormalities)

Moderate	Bileaflet aortic valve prosthesis and one of the following: atrial fibrillation, prior stroke or transient ischemic attack, hypertension, diabetes, congestive heart failure, age >75 years	CHADS$_2$ score of 3 or 4	VTE within the past 3 to 12 months (consider VTE prophylaxis rather than full intensity bridge therapy) Nonsevere thrombophilic conditions (e.g., heterozygous factor V Leiden mutation, heterozygous factor II mutation) Recurrent VTE Active cancer (treated withi 6 months or palliative)
Low	Bileaflet aortic valve prosthesis without atrial fibrillation and no other risk factors for stroke	CHADS$_2$ score of 0 to 2 (no prior stroke or transient ischemic attack)	Single VTE occurred greate than 12 months ago and no other risk factors

VTE, venous thromboembolism.

Table 11-26

Bleed Risk of Selected Procedures

Low Risk (2-Day Major Bleed Risk of 0%–2%)	**High Risk (2-Day Major Bleed Risk of 2%–4%)**
Abdominal hernia repair	Abdominal aortic aneurysm repair
Cataract surgery	Any surgery lasting > 45 minutes
Cholecystectomy	Major cancer surgery
Colonoscopy	Major cardiac surgery (heart valve replacement & CABG)
Cutaneous biopsies	Major orthopedic surgery (joint replacement)
Cystoscopy	Major vascular surgery
Dilation and curettage	Transurethral prostate resection
Dental extractions	Neurosurgical procedures
GI endoscopy ± biopsy	Polypectomy, variceal treatment
Skin cancer excision	Renal biopsy

Adapted from Spyropoulos AC. Perioperative bridging therapy for the at-risk patient on chronic anticoagulation. Dis Mon. 2005;51:183–193.

Because L.P. has a mechanical mitral valve replacement, her risk of thromboembolism associated with underanticoagulation is considered high. Therefore, she should receive bridge therapy with an injectable anticoagulant while warfarin is held. Her renal function is normal, and her healthcare insurance covers injectable drugs. Therefore, her plan will include early discontinuation of warfarin 5 days before the procedure and substitution with enoxaparin 1 mg/kg every 12 hours when the INR falls below the lower limit of the therapeutic range. The last dose of enoxaparin should be given 24 hours before the procedure to minimize the risk of bleeding at the time of the procedure. After the procedure, warfarin should be restarted at her usual dose, and enoxaparin should be continued until the INR is greater than 2.5, the lower limit of L.P.'s therapeutic range. For indications other than mechanical valves, enoxaparin 1.5 mg/kg every 24 hours may be used as an alternative to avoid twice-daily injections.

DRUG INTERACTIONS

Interactions with Prescription Drugs

CASE 11-13

QUESTION 1: P.T., a 48-year-old woman, received a mechanical mitral valve prosthesis 5 years ago and has been anticoagulated with warfarin 6 mg/day with good control. She asks to see you today in your anticoagulation clinic, after returning from an urgent appointment with her primary care physician for treatment of a skin infection that tested positive for community-acquired methicillin-resistant Staphylococcus aureus (MRSA), and was given a prescription for trimethoprim–sulfamethoxazole (TMP-SMX) twice a day for 10 days today. She is allergic to penicillin and has gastric intolerance to tetracycline. How will the combination of warfarin and TMP-SMX affect P.T.'s anticoagulation control? Should her warfarin dosage be adjusted or another drug substituted for TMP-SMX?

Table 11-27

Bridge Therapy Guidelines of Invasive Procedures

	Action		
Day	**Warfarin**	**LMWH**	**Laboratories**
−6	Last warfarin dose	N/A	INR; skip dose if supratherapeutic
−5	No warfarin	N/A	
−4	No warfarin	Start LMWH	
−3	No warfarin	LMWH	
−2 to −1	No warfarin	LMWH; last dose 24–36 hours prior to procedure	
0—day of procedure	Resume warfarin at usual dose if hemostasis is achieved[a]	No LMWH	Ensure INR is appropriate for surgery[b] CBC
1	Resume warfarin if not started day prior	LMWH; resume following minor surgery No LMWH following	

		major surgery	
2–3	Warfarin	LMWH; resume following major surgery if bleeding controlled	
4	Warfarin	LMWH	
5–7	Warfarin	LMWH	INR; discontinue when therapeutic Consider CBC, CrCl, anti-Xa level with continued need for LMWH

[a] Consider giving 1.5 times usual warfarin dose for first 2 days when warfarin reinitiated.

[b] INR < 1.5 required for most surgical procedures.

INR, international normalized ratio; LMWH, low-molecular-weight heparin; CBC, complete blood count; CrCl, creatinine clearance.

Drug interactions with warfarin occur by a number of different mechanisms and can have a significant impact on the anticoagulant effect of warfarin.[148,149] Elevations or reductions in INR have been observed when interacting drugs are added to or discontinued from the medication regimens of patients taking warfarin or when used intermittently. Clinically significant hemorrhagic or thromboembolic complications can result. Careful selection of both prescription and nonprescription medications, appropriate INR monitoring, and detailed patient education regarding drug interactions are important interventions for pharmacists caring for patients taking warfarin. A selection of the hundreds of drugs that have been reported to interact with warfarin, including mechanisms of interaction and effect on INR, is provided in Table 11-28. Further information regarding the management of drug interactions can be found in Chapter 3, Drug Interactions.

Table 11-28

Warfarin Drug Interactions

Target	Effect	Response	Examples (Not Inclusive)			
Clotting factors	Increased synthesis	Decreased INR	Vitamin K			
	Decreased synthesis	Increased INR	Broad-spectrum antibiotics			
	Increased catabolism	Increased INR	Thyroid hormones			
	Decreased catabolism	Decreased INR	Methimazole		Propylthiouracil	
Warfarin	Inhibition	Increased	Acetaminophen	Allopurinol	Amiodarone	Azole

metabolism		INR				antifungals
			Cimetidine	Fluoroquinolones	Macrolides	Metronidazole
			Propafenone	SSRIs	Statins	Sulfa antibiotics
	Induction	Decreased INR	Barbiturates	Carbamazepine	Doxycycline	Griseofulvin
			Nafcillin	Phenytoin	Primidone	Rifampin
Hemostasis	Additive antithrombotic effects	Increased bleeding risk	Aspirin	NSAIDs	Salicylates	GPIIb/IIIa inhibitors
	Additive anticoagulant response	Increased bleeding risk	Heparin	LMWH	Direct thrombin inhibitors	Thrombolytics
		Decreased INR	Cholestyramine	Colestipol	Sucralfate	
Absorption	Reduced	Decreased INR	Ascorbic acid	Azathioprine	Corticosteroids	Cyclosporine
Unknown		Increased INR	Androgens	Fenofibrate	Cyclophosphamide	Gemfibrozil

GP, glycoprotein; INR, international normalized ratio; LMWH, low-molecular-weight heparin; NSAIDs, nonsteroidal anti-inflammatory drugs.

Although warfarin is highly bound to protein (primarily to albumin), and can be displaced from protein-binding sites by a number of weakly acidic drugs, these interactions typically do not result in clinically significant elevations in PT/INR.[150] Warfarin displaced from protein-binding sites is readily available for elimination by hepatic metabolism, resulting in increased clearance without a significant change in the free drug concentration.

Other types of interactions with warfarin are much more significant. Pharmacodynamic interactions are those that alter the physiology of hemostasis, particularly interactions that influence the synthesis or degradation of clotting factors or that increase the risk of bleeding through inhibition of platelet aggregation. Pharmacokinetic interactions influence the absorption and metabolism of warfarin, and many clinically significant interactions with warfarin occur when warfarin metabolism is induced or inhibited. Interactions involving agents known to influence the hepatic microsomal enzyme systems responsible for the metabolism of the more potent S(−)-warfarin (CYP2C9) are more significant than those that influence the enzymes that metabolize R(+)-warfarin (CYP1A2, CYP3A4).

Sulfamethoxazole can increase the effect of warfarin significantly by stereoselectively inhibiting the metabolism of the more potent S(−)-enantiomer of warfarin. Potentiation of warfarin activity after inhibition of metabolism usually takes several days, and the effect may be slow to resolve once the offending agent is discontinued. In addition, fever associated with the infection for which TMP-SMX has been prescribed may enhance the catabolism of vitamin K-dependent clotting factors, resulting in an accentuated hypoprothrombinemic response. This effect will dissipate as the fever abates with antibiotic therapy.

For P.T., the ideal choice would be to discontinue TMP-SMX and use a noninteracting alternative. The decision of which agent to use must consider both the treatment(s) of choice for the clinical indication along with patient factors such as reported allergies or intolerances. In P.T.'s case, she has a penicillin allergy and intolerance to tetracyclines, both of which would prevent their use. If a noninteracting alternative is not clinically appropriate, the concomitant use of an interacting agent is not absolutely contraindicated in patients taking warfarin. Use of TMP-SMX in P.T. would be acceptable if she is monitored frequently and carefully, with adjustment of warfarin dosages as necessary to maintain her INR within the therapeutic INR range of 2.5 to 3.5 and with attention to potential hemorrhagic complications. No initial change in the dosage of warfarin should be made because it may take several days for the interaction to become apparent. The INR should be repeated within 3 days, with warfarin dosing adjustments and subsequent monitoring guided by initial INR results.

CASE 11-14

QUESTION 1: G.H. is a 54-year-old man on long-term anticoagulation for multiple, bilateral DVTs, most recently 1 year ago, for which he takes warfarin 7.5 mg daily. He had a knee replacement surgery 6 months ago and had a complication of infected hardware, for which he needs to start IV rifampin in a skilled nursing facility for several weeks. His orthopedic physician is asking about whether G.H. can be switched to an alternate anticoagulant, because he knows that there is a drug interaction with warfarin and rifampin. What options are available to him?

Although the DOACs are less prone to drug interactions than warfarin, all of them are P-glycoprotein substrates and can have their concentrations reduced by rifampin, which is a strong P-gp inducer.[151] At this time, dabigatran, rivaroxaban, apixaban, and edoxaban are all contraindicated with rifampin per package labeling and are not suitable options for G.H.

The interaction with warfarin and rifampin can be significant, with a potentially large dose increase (sometimes up to 3 times the original dose) of warfarin necessary to maintain G.H. in the therapeutic range. If G.H. is in a facility where his INRs can be measured frequently, such as every few days, it may be appropriate to maintain him on warfarin while continuing the rifampin, until the degree of the interaction can be detected, and a new stable dose can be determined. Alternatively, if G.H. is receiving the antibiotics at home, it may be appropriate for him to acquire a home INR meter and perform warfarin self-testing of his INRs. It has been shown that individuals performing patient self-testing (almost all testing weekly) had better time in therapeutic range (TTR) than those who underwent in-clinic testing every 4 weeks using high-quality anticoagulation management.[152] A substudy of this trial also showed that individuals on chronic anticoagulation who perform self-testing more often (i.e., weekly or twice weekly) had a modestly higher TTR compared to monthly testing.[153] The costs of the self-testing meter and supplies are often covered by the patient's insurance; however, sometimes the poor reimbursement for managing anticoagulation services this way can limit providers' willingness to offer patient-self testing. If reimbursement is not a concern (such as in a closed insurance system), then patient self-testing can be a way to empower patients to take more control of their warfarin management and reduce the burden of INR monitoring.

LMWH, UFH, and fondaparinux are also reasonable options for G.H. to use, especially if his INRs cannot be stabilized while receiving the rifampin. However, again, there could be barriers to self-injection and insurance limitations that may make it difficult to continue these agents for a prolonged length of time.

CASE 11-14, QUESTION 2: Can G.H. return to using his ibuprofen for pain control?

This question illustrates one of the most difficult therapeutic dilemmas for a patient taking warfarin. All NSAIDs have the potential to cause gastric irritation by inhibiting cytoprotective prostaglandins, thereby providing a focus for GI bleeding. In addition, most NSAIDs inhibit platelet aggregation, which compromises effective clotting and can lead to bleeding complications.[154]

These effects can increase the risk of hemorrhagic complications significantly in patients taking warfarin who are prescribed concurrent NSAID therapy. In a retrospective cohort study of patients age 65 years or older, the risk of hospitalization for bleeding peptic ulcer disease was approximately 3 times higher for patients taking concurrent warfarin and an NSAID versus patients taking either drug alone, and almost 13 times higher than in patients taking neither warfarin nor an NSAID.[155] Warfarin therapy is considered a relative contraindication to NSAID use.

In patients like G.H., routine use of NSAIDs with long-term anticoagulation should be avoided. Any patients requiring combined warfarin and NSAID therapy for limited periods of time should be followed closely and observed routinely for signs and symptoms of bleeding, with frequent stool testing for GI bleeding. Patients should be counseled to avoid additional NSAID use whenever possible, including use of aspirin, and to seek assistance from a pharmacist to prevent inadvertent NSAID use when selecting over-the-counter (OTC) medications, as some OTC cold preparations contain NSAIDs, aspirin, or aspirin-related compounds.

The analgesic and antipyretic of choice in patients taking warfarin is acetaminophen, which has not been consistently shown to increase the risk of bleeding. At doses greater than 2 g/day, acetaminophen can enhance the anticoagulant effect of warfarin.[156] It has been suspected of directly inhibiting CYP2C9 and CYP1A2, and toxic metabolites of acetaminophen have been suspected of inhibiting hepatic enzymes as well. Nevertheless, it can be used safely when used occasionally, and even when used routinely. INR monitoring is sufficient to detect any potential interaction. Other pain-relieving options to be considered that do not increase the bleeding risk include tramadol, gabapentin, pregabalin, topical lidocaine patches, and opiates.

Chronic Stable Angina

Angela M. Thompson and Toby C. Trujillo

CORE PRINCIPLES

CHRONIC STABLE ANGINA—MEDICAL MANAGEMENT

		CHAPTER CASES
1	Chronic stable angina is a clinical syndrome resulting from an imbalance in myocardial oxygen supply and demand. The supply–demand imbalance is typically a result of coronary atherosclerosis.	**Case 12-1 (Questions 1–3)**
2	The modification of cardiovascular disease (CVD) risk factors and adoption of healthy lifestyles is a key strategy in both the primary prevention of coronary artery disease (CAD) and slowing the progression of established CAD.	**Case 12-1 (Questions 7–9)** **Case 12-2 (Question 2)**
3	Standard therapy for all patients with chronic stable angina includes sublingual nitroglycerin, antiplatelet therapy, and an anti-ischemic agent that either restores the appropriate balance of myocardial oxygen supply and demand (β-blockers, calcium-channel blockers, and long-acting nitrates), and/or interrupts the negative consequences of myocardial ischemia on myocardial energy consumption (ranolazine).	**Case 12-1 (Questions 10–14, 16)** **Case 12-3 Question 2)**
4	β-Blockers are the preferred initial agents for prevention of ischemic symptoms, especially in patients who have a history of myocardial infarction (MI) or heart failure.	**Case 12-1 (Questions 11, 12, 13, 15)**
5	Although effective as monotherapy, long-acting calcium-channel blockers are typically added on to β-blocker therapy if additional control of ischemic symptoms is needed.	**Case 12-2 (Question 1)**
6	Long-acting nitrates should never be used as monotherapy but can be used as add-on therapy to other anti-ischemic options in chronic stable angina.	**Case 12-1 (Questions 16–19)**
7	Although ranolazine can be used as initial therapy for chronic stable angina, it is typically reserved as a second-line option. It is especially useful in patients who cannot tolerate further decreases in heart rate and blood pressure secondary to the use of traditional antianginal agents.	**Case 12-2 (Questions 3, 4)**

CHRONIC STABLE ANGINA—REVASCULARIZATION

1	Myocardial revascularization can be accomplished either through percutaneous coronary intervention (PCI) or coronary artery bypass	**Case 12-3 (Question 5)**

	surgery (CABG). In most patients, both are equally effective in reducing myocardial ischemia.	
②	Certain patients who are at high risk for morbidity and mortality from CAD derive a mortality benefit with CABG as compared to PCI or medical management.	**Case 12-3 (Question 5)**
③	In patients not at high risk, optimal medical management is as good as PCI in the long-term management of chronic stable angina, including the prevention of MI and death.	**Case 12-1 (Question 6)**
④	Patients who undergo myocardial revascularization either with PCI or CABG should still receive optimal pharmacotherapy for chronic stable angina.	**Case 12-3 (Question 6)**

---

⑤	Appropriate pharmacotherapy for patients undergoing elective PCI plus myocardial stent implantation should include dual antiplatelet therapy with aspirin and a $P2Y_{12}$ antagonist, in most cases clopidogrel therapy, for a minimum of 1 month (bare-metal stent) and ideally up to 1 year (bare-metal and drug-eluting stents).	**Case 12-3 (Question 3)**
⑥	Antiplatelet nonresponsiveness has been demonstrated to be associated with an increased risk for cardiovascular events such as MI and death. An understanding of various testing modalities for antiplatelet response, as well as potential drug–drug interactions that may lead to reduced antiplatelet activity will facilitate optimal pharmacotherapy in each patient.	**Case 12-3 (Questions 6, 7)**
	PRINZMETAL ANGINA/CARDIAC SYNDROME X	
①	Patients with Prinzmetal angina and cardiac syndrome X typically present with severe chest pain despite having coronary arteries that are free from atherosclerosis.	**Case 12-4 (Question 1)**
②	Vasodilators are the primary mode of therapy for patients with Prinzmetal angina, while standard anti-ischemic options should be used for cardiac syndrome X.	**Case 12-4 (Questions 2, 3)** **Case 12-5 (Question 1)**

CHRONIC STABLE ANGINA

Coronary heart disease (CHD) includes heart failure (HF), arrhythmias, sudden cardiac death, and ischemic heart disease (IHD) such as myocardial infarction (MI) as well as unstable and stable angina pectoris. Because angina is a marker for underlying heart disease, its management is of great importance. Typical angina pectoris is characterized by substernal chest, jaw, shoulder, back, or arm pain triggered by exertion or stress, and it is relieved by rest or nitroglycerin (NTG); however, its presentation is variable.[1,2]

Patients who have a reproducible pattern of angina that is associated with a certain level of physical activity have chronic stable angina or exertional angina. In contrast, patients with unstable angina experience new-onset angina or a change in their angina intensity, frequency, or duration.[3] Both chronic stable angina and unstable angina often reflect underlying atherosclerotic narrowing of coronary arteries on coronary angiography. In contrast, Prinzmetal variant angina is associated with normal findings on coronary angiography and is thought to be caused by a spasm of the coronary artery that decreases myocardial blood flow. The presence of atherosclerosis also may lead to impairment of the normal vasodilatory function of the coronary arteries. As such, coronary artery disease (CAD) patients who experience ischemia produced by an increase in myocardial oxygen demand (increased exertion) may also experience vasospasm at the site of atherosclerosis, further worsening the ischemic state. As such, patients with CAD likely experience angina due to both increased demand (exertion) and decreased supply (vasospasm), a phenomenon known as mixed angina.[3]

Silent (asymptomatic) myocardial ischemia can result in transient changes in myocardial perfusion, function, or electrical activity, and is detected on an electrocardiogram (ECG).[3] The patient, however, does not experience chest pain or other signs of angina during these episodes.

Epidemiology

It is estimated that 85.6 million adults in the United States have cardiovascular disease (CVD),[1] and 15.5 million of these adults have CHD.[4] Chronic stable angina is the first clinical sign of CHD in approximately 50% of patients.[1] Current estimates indicate 8.2 million American adults have angina pectoris, although the prevalence of angina is likely underestimated due to limited population-based data and because it is often unrecognized in patients.[4]

CVD is the leading cause of death in the United States responsible for one of every three deaths[4] Although CHD accounts for one of every seven deaths in the United States, individual mortality varies according to the patient's age, sex, cardiovascular risk profile, myocardial contractility, coronary anatomy, and specific anginal syndrome.[4]

In addition to the high morbidity and mortality associated with CHD, the economic cost to the US health care system is substantial. Total direct and indirect costs associated with CHD were estimated to be $204.4 billion in 2010, and direct medical costs for CHD are expected to increase by 100% between 2013 and 2030.[4]

Pathophysiology

A brief review of coronary anatomy will facilitate a thorough understanding of the pathophysiology of chronic stable angina. Figure 12-1 illustrates the normal distribution of the major coronary arteries, although variation is common between individuals.

Angina pectoris typically occurs from myocardial ischemia. Ischemia in the myocardium develops when there is a mismatch between myocardial oxygen supply and demand. The underlying pathologic condition of this mismatch invariably is the presence of atherosclerosis in one or more of the coronary arteries.[3]

MYOCARDIAL OXYGEN SUPPLY AND DEMAND

The oxygen demand of the heart is determined by its workload. The major determinants of myocardial oxygen consumption are heart rate, contractility, and intramyocardial wall tension during systole (Fig. 12-2).[3,5] Intramyocardial wall tension, the force the heart is required to develop and sustain during contraction, is affected primarily by changes in ventricular pressures and volume. Both enlargement of the ventricle and increased pressure within the ventricle increase the systolic wall force and consequently myocardial oxygen demand. Increases in contractility and heart rate also increase oxygen demand.[6] Pharmacologic control of angina is directed toward decreasing the myocardial oxygen demand by decreasing heart rate, myocardial contractility, or ventricular volume and pressures.[3,5]

Figure 12-1 Coronary arteries. The right coronary artery (RCA) originates from the aorta and courses in the atrioventricular (coronary) groove to reach the posterior surface of the heart. The left coronary artery splits into the circumflex branch that supplies blood to the lateral and posterior walls of the left ventricle, and a left anterior descending (LAD) branch that supplies blood to the anterior wall of the left ventricle. **A:** Anterior view. **B:** Posteroinferior view.

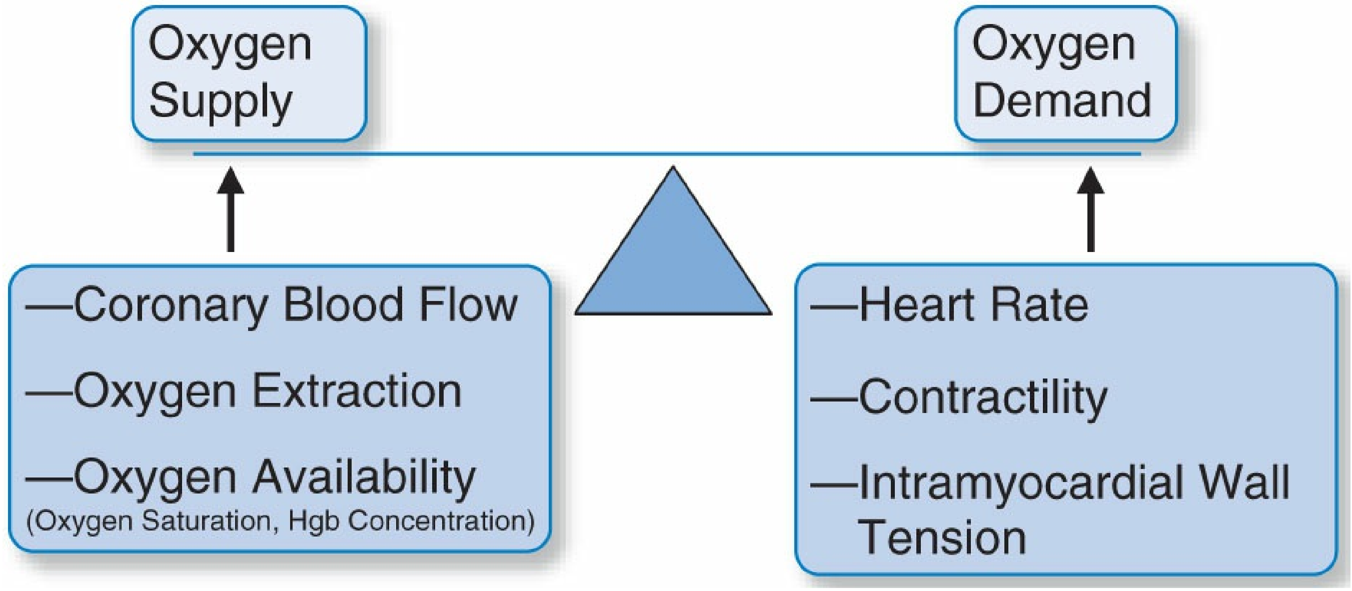

Figure 12-2 Determinants of myocardial oxygen supply and demand.

Oxygen supply to the heart is impacted by many factors including coronary blood flow and oxygen extraction (Fig. 12-2). Oxygen extraction by heart cells is high (~70%–75%) even at rest. When extra demand is placed on the heart, myocardial oxygen extraction increases slightly and plateaus at approximately 80%. Because oxygen extraction is increased only modestly when the heart is stressed, high oxygen demands must be met by increases in coronary blood flow.[7] The oxygen content of arterial blood also is important. Therefore, the hematocrit (Hct), hemoglobin (Hgb), and arterial blood gases should be monitored. In a similar fashion to targeting determinants of myocardial oxygen demand, pharmacologic control of angina is directed at improving oxygen supply through vasodilation of the epicardial coronary arteries.[5]

ATHEROSCLEROTIC VASCULAR DISEASE

Although understanding the determinants of myocardial oxygen supply and demand is important in treating CHD, of equal importance is understanding how atherosclerotic plaques develop because the underlying pathologic condition of this mismatch invariably is the presence of atherosclerosis in one or more of the coronary arteries. Understanding how the process of atherosclerosis unfolds, as well as the primary pharmacologic and non-pharmacologic interventions that help prevent progression of atherosclerosis, is an important piece in treating a patient with chronic stable angina (Fig. 12-3). (See Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease.)

If an atherosclerotic plaque occludes less than 50% of the diameter of the vessel, coronary blood flow can be augmented sufficiently during exertion by the intramyocardial arterioles (resistance vessels), and the patient is pain free. In patients with chronic stable angina, most coronary artery stenoses are greater than 70%.[3,5]

Traditional risk factors, such as smoking, hypertension, hyperlipidemia, diabetes, and obesity, are linked to the process of atherosclerosis by producing oxidative stress within the vasculature. Increased oxidative stress leads to progressive decreases in nitric oxide (NO) levels and endothelial dysfunction, enhancing atherosclerosis (Fig. 12-4).[8] In addition, diets typically seen in western industrialized countries have been linked to increased oxidative stress within the vasculature. This may partially explain the link between diet and atherosclerosis.[9] The role of a healthy lifestyle and diet is crucial in preventing the development or progression of CAD.

Although traditional risk factors have long been appreciated as the underlying cause for the development of CAD, continuing research efforts have attempted to identify novel risk factors to refine risk assessment for the development of CAD. Potential candidates have included highly-sensitive C-reactive protein, homocysteine, fibrinogen, and lipoprotein (a), among others.[10,11] Findings from the INTERHEART study indicate little may be gained from identifying additional risk factors.[12] In this large case–control study, nine clinical risk factors were strongly associated with the development of first-ever MI and accounted for greater than 90% of the risk for developing CAD (Table 12-1). The results were consistent across sex, geographic regions, and ethnic groups, suggesting that strategies to reduce the incidence of CAD can be applied universally. Subsequent studies have verified the findings of INTERHEART, and many of these potential risk factors may indeed more accurately reflect the presence of CAD and be considered markers, as opposed to predicting who will subsequently exhibit CAD.[10,11,13]

PLATELET AGGREGATION AND THE FORMATION OF THROMBI

Although coronary atherosclerosis is the underlying mechanism for most patients with anginal syndromes, thrombotic factors commonly play a key role in the pathogenesis of myocardial ischemia. Both blood flow turbulence and stasis can cause intermittent platelet aggregation or intermittent coronary artery thrombosis. Thus, platelet-active agents are used in the treatment of chronic stable angina.[14]

Table 12-1

Risk Factors for First-Time Myocardial Infarction from the INTERHEART Study[12]

Risk Factor	Adjusted Odds Ratio (99% Confidence Interval)
ApoB to apoA-1 ratio[a]	3.25 (2.81–3.76)
Current smoking	2.87 (2.58–3.19)
Psychosocial	2.67 (2.21–3.22)
Diabetes	2.37 (2.07–2.71)
Hypertension	1.91 (1.74–2.10)
Abdominal obesity	1.62 (1.45–1.80)
Moderate alcohol intake	0.91 (0.82–1.02)
Exercise	0.86 (0.76–0.97)
Vegetables and fruits daily	0.70 (0.62–0.79)
All combined	129.2 (90.2–185.0)

Apo, apolipoprotein.

[a] Risk of MI increases with increased ratio.

INTRACELLULAR SODIUM AND CALCIUM HANDLING

Recently, an appreciation has emerged for the role of the late sodium current (I_{Na}) in the development and maintenance of myocardial ischemia. Most sodium enters the myocardium in phase 0 of the action potential. Under normal conditions, however, a small amount of sodium will enter the cell during phase 2 (plateau phase) of the action potential. When ischemia is present, sodium handling is altered such that a substantial increase occurs in the late I_{Na}. The increase in intracellular sodium triggers an increase in the influx of calcium through the reverse mode of the sodium–calcium exchanger. The net result of the alterations in intracellular ion handling is intracellular calcium overload.[5] Increases in intracellular calcium impair myocardial relaxation, increase intramyocardial wall tension, decrease perfusion to the myocardium owing to compression of the small arterioles feeding the myocardium, and increase myocardial oxygen demand.[15] Ultimately, these pathologic changes in sodium and calcium handling perpetuate and worsen ischemia once it develops. Targeting this pathologic process has led to the development of new antianginal medications (e.g., ranolazine) with a distinct, novel mechanism of action compared with traditional antianginal agents (i.e., nitrates, β-blockers, and calcium-channel blockers [CCBs]).[5]

Clinical Presentation

A detailed description of chest pain is vital in order for the clinician to determine whether chest pain represents chronic stable angina, Acute Coronary Syndrome (ACS), or is noncardiac in origin. Five key components commonly used to characterize chest pain include the location, duration, severity, and quality of pain, as well as any factors that provoke and relieve the pain (Table 12-2). Chest pain stemming from myocardial ischemia is often described as a sensation of pressure or heavy weight located over the sternum. Patients may also complain of shortness of breath (SOB), nausea, vomiting, or diaphoresis. Pain may also occur in the neck, jaw, shoulder, or arm. The precipitation of pain is typically associated with exertion and rapidly resolves with rest or the administration of NTG. Chest pain that occurs at rest, prolonged in duration, or increased in severity is likely reflective of unstable disease and warrants immediate medical attention to prevent complications such as MI, HF, and death. Importantly, some patients (women, people with diabetes) may present with atypical symptoms such as indigestion or gastric fullness, or may present with diaphoresis alone without concomitant chest pain. Last, many episodes of ischemia are asymptomatic and termed as “silent ischemia.”[1–3]

Physical findings in patients with chronic stable angina are often absent or nonspecific.[1]

Diagnosis and Risk Assessment

The evaluation of a patient presenting with chest pain suspected to be due to CAD should begin with a detailed history of ischemic symptoms and physical examination. Once this information is available, an estimate can be made of the probability of CAD being present (low, intermediate, high).[1] The probability estimate will often help direct which diagnostic tests are appropriate. Given that many symptoms associated with chronic stable angina are nonspecific, several noninvasive and invasive testing modalities are available to assist in the diagnosis and risk assessment of CAD.[1,2] It is important to discern as soon as possible whether the patient’s reported chest discomfort is consistent with chronic stable angina, or represents the presence of ACS. Patients presenting with ACS often are at high short-term risk of MI or death and warrant hospitalization with aggressive treatment strategies.[16,17] Lipid parameters, renal function, and fasting blood glucose levels should be obtained in all patients with suspected or established CAD to screen for metabolic abnormalities. Other biochemical markers such as high-sensitivity C-reactive protein, lipoprotein(a), lipoprotein-associated phospholipase A_2, and apolipoprotein B are not routinely recommended.[3]

Table 12-2

Characteristics of Angina Pectoris[1–3]

Symptoms
Sensation of pressure or heavy weight on chest alone or with pain Pain described variably as feelings of tightness, burning, crushing, squeezing, vicelike, aching, or "deep"
Gradual increase in intensity followed by gradual fading away (distinguished from esophageal spasm)[a]
Shortness of breath with feeling of constriction about the larynx of upper trachea
Duration of Symptoms
0.5–30 minutes
Location of Pain or Discomfort
Over the sternum or very near to it Anywhere between epigastrium and pharynx
Occasionally limited to left shoulder and left arm
Rarely limited to right arm
Lower cervical or upper thoracic spine
Left interscapular or suprascapular area
Radiation of Pain
Medial aspect of left arm Left shoulder
Jaw
Occasionally, right arm
Electrocardiogram
ST-segment depression >2 mm T-wave inversion
Precipitating Factors
Mild, moderate, or heavy exercise, depending on patient Effort that involves use of arms above the head
Cold environment
Walking against the wind
Walking after a large meal
Emotions: fright, anger, or anxiety
Coitus
Nitroglycerin Relief[a]
Relief of pain occurring within 45 seconds to 5 minutes of taking nitroglycerin

[a] Esophageal spasm and other gastrointestinal disorders occasionally mimic anginal pain and also can be relieved by nitroglycerin.

A 12-lead ECG reading should be obtained in all patients with symptoms suggestive of angina pectoris. Although not useful in establishing a definitive diagnosis of CAD, the ECG will be useful at detecting important information regarding conduction abnormalities, left ventricular hypertrophy, ongoing ischemia, or evidence of a previous MI. Chest radiography is not routinely recommended except in patients with an abnormal ECG, history of MI, symptoms of HF, or ventricular arrhythmias.[1] Cardiac computed tomography angiography (CCTA) is a reasonable option to determine risk in patients whose ECG cannot be interpreted, who are unable to exercise to an appropriate workload, unable to perform stress testing, or alternatively to invasive coronary angiography in moderate- to high-risk patients with unknown coronary anatomy.[1]

STRESS TESTING

The induction of stress via exercise or pharmacologic means is a common and highly useful procedure in the diagnosis of CAD. The test would be indicative of CAD if angina, ECG signs of ischemia, arrhythmias, abnormal heart rate, or abnormal blood pressure (BP) response develops. The product of the heart rate and systolic BP (i.e., the rate–pressure or double product) correlates well with myocardial oxygen demand. The rate–pressure product normally rises progressively during exercise, with the peak value best describing the cardiovascular response to stress. Often, patients with stable angina experience chest pain at a consistent rate–pressure product.[18]

Abnormal responses of either BP or heart rate may signal CAD. A normal BP response to exercise is a gradual rise in systolic BP with the diastolic BP remaining unchanged. A rise or fall of diastolic BP greater than 10 mm Hg is considered abnormal. A fall in systemic BP during exercise is especially ominous because this indicates that the cardiac output cannot increase sufficiently to overcome the vasodilation in the skeletal muscle vascular bed.[18]

Stress imaging studies, either echocardiographic or nuclear, are preferred over the exercise tolerance test in patients with left bundle-branch block, electronically paced ventricular rhythm, prior revascularization (percutaneous coronary intervention [PCI] or coronary artery bypass surgery [CABG]), preexcitation syndrome, greater than 1 mm ST-segment depression at rest, or other ECG conduction abnormalities. In addition, many patients are not able to exhibit an appropriate level of cardiac stress through exercise; pharmacologic stress testing is preferred in these patients.[1,18]

Pharmacologic stress may be achieved through the use of dipyridamole, adenosine, or dobutamine. Each of these agents is used to induce changes in the balance between myocardial oxygen supply and demand, similar to walking on a treadmill during the exercise stress test. Vasodilators (dipyridamole and adenosine) promote vasodilation in normal coronary segments, but have no effect in arteries affected by atherosclerosis. The net result is shunting of blood away from diseased coronary arteries and the development of ischemia that may be detected by changes in BP, heart rate, or ECG changes. These agents are typically used in conjunction with myocardial perfusion scintigraphy. Stress thallium-201 myocardial perfusion imaging provides a dynamic picture of the heart. The radionuclide is injected at peak stress and an image is obtained within several minutes. A defect in myocardial uptake of the thallium indicates an area of ischemia or possible infarction.[19]

Dobutamine is a positive inotrope and typically is used with echocardiography. Administration of dobutamine leads to an increase in myocardial oxygen demand secondary to increases in heart rate and contractility. If demand exceeds available oxygen supply, ischemia develops. Subsequent to the infusion of dobutamine, defects or decreases in the wall motion or thickening of the left ventricle are indicative of ischemia.[19]

CARDIAC CATHETERIZATION

CAD can be diagnosed definitively by coronary catheterization and angiography. In addition, angiography is the most accurate means of identifying less common causes of chronic stable angina, such as coronary artery spasm.[1] Cardiac catheterization is a procedure used to provide vascular access to the coronary arteries. Once access is gained with an intravascular catheter, a number of procedures (angiography, ventriculography, PCI) can be performed. Access to the vasculature is usually obtained percutaneously through the radial, brachial, or femoral arteries. From this point, the catheter is advanced through the vasculature until the coronary arteries are accessible. After the tip of the catheter is advanced into the coronary arteries, dye is injected into the coronary arteries and the location and extent of atherosclerosis can be determined. Approximately 75% of patients with chronic stable angina are noted to have one-vessel, two-vessel, or three-vessel disease by this procedure (equally divided).[3]

The results of angiography can be useful in determining the risk of death or MI in patients with CAD and, subsequently, the course of needed treatment. For example, patients who have a significant stenosis in the left main coronary artery are at high risk of death and should undergo CABG.[20,21]

OVERVIEW OF DRUG AND NONDRUG THERAPY

The goals of therapy for chronic stable angina are to reduce or eliminate the symptoms of angina, to maintain or improve the quality of life, halt the progression of atherosclerosis and prevent complications of the disease, such as MI and death while minimizing healthcare costs. Both pharmacologic and non-pharmacologic interventions, in addition to myocardial revascularization procedures, are utilized simultaneously to achieve each of these goals.[1]

Vasculoprotective Therapy

LIFESTYLE MODIFICATIONS

Lifestyle modifications should always constitute a significant portion of any treatment plan for patients with chronic stable angina. Lifestyle modification should include adoption of a heart-healthy diet, smoking cessation/avoidance of second-hand smoke, adequate physical activity, weight control, and maintenance of an acceptable waist circumference.[1,22,23] Dietary recommendations typically consist of limiting saturated fat, total fat, cholesterol, sodium, sugar-sweetened beverages, and red meat while consuming a diet high in fruits, vegetables, whole grains, omega-3 fatty acids, and fiber[22] (see Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease). Adoption of a healthy dietary pattern reflective of these components has been demonstrated to have positive effects on cardiovascular risk factors.[1,22]

Smoking cessation is a crucial intervention as cigarette smoking (including second-hand smoke exposure) has been identified as the single most preventable cause of death due to CAD.[24] Clinicians should routinely assess the smoking status of patients with chronic stable angina and provide information regarding effective options to aid in smoking cessation. Nicotine replacement products, bupropion, and varenicline have been demonstrated as effective in assisting cessation efforts (see Chapter 91, Tobacco Use and Dependence). In addition to the avoidance of cigarette smoke, it is reasonable to recommend the avoidance of air pollution in patients with chronic stable angina. Unless contraindicated, it is appropriate to recommend one alcoholic beverage in women and one to two alcoholic beverages in men.[1]

A body mass index (BMI) of 18.5 to 24.9 kg/m^2 and a waist circumference less than 40 inches in men and 35 inches in women should be achieved or maintained. Adequate exercise facilitates both weight loss and better control of cardiovascular risk factors. Patients with chronic stable angina should be encouraged to engage in moderate-intensity exercise for 30 to 60 minutes/day for at least 5 days/week, but ideally each day. Weight loss can be facilitated through appropriate caloric restriction, as well as the adoption of healthy dietary eating patterns.[1]

RISK FACTOR MODIFICATION

In addition to appropriate lifestyle modifications, optimization of cardiovascular risk factors should be achieved. Although the lifestyle modifications may help improve risk factor control, pharmacotherapy may be required. Table 12-3 provides appropriate targets for risk factor optimization. Appropriate identification and treatment of risk factors helps prevent the development of CAD and disease progression in patients with existing CAD. Select drug therapies for each risk factor may be preferred due to their positive effects on the pathophysiology of atherosclerosis. Although several different classes of lipid-modifying drugs exist, 3-

hydroxy-3-methylglutaryl co-enzyme A inhibitors (HMG-CoA reductase inhibitors, or statins) have been demonstrated in multiple trials to significantly reduce the progression of atherosclerosis, as well as reduce the incidence of death and MI.[25] In patients who require additional BP control after antianginal therapy has been optimized, angiotensin-converting enzyme (ACE) inhibitors may be preferred due to their theoretical potential to reduce the progression of CAD by improving endothelial function. Data suggest that angiotensin receptor blockers (ARBs) may provide similar benefits in patients who cannot tolerate ACE inhibitors.[1,26] The presence of diabetes has been shown to be a significant risk factor for the development and progression of atherosclerosis; however, the majority of clinical trials demonstrate that tight glycemic control did not have a positive effect on the progression of atherosclerosis or reduce the risk of hard end points such as MI.[27] Information from the Diabetes Control and Complications Trial indicates that tight glycemic control with intensive insulin therapy in patients with type 1 diabetes significantly reduces the risk for MI and cardiovascular death.[28] Similar effects have not been seen in large randomized trials in patients with type 2 diabetes. In one large trial involving patients with CVD and type 2 diabetes, the use of intensive insulin therapy reduced nonfatal MI at 5 years, but total mortality was increased.[29] Given the available information, intensive glucose lowering cannot be recommended for patients with CAD and type 2 diabetes. Patients with type 2 diabetes should target a glycosylated hemoglobin (Hgb A_{1c}) less than 7%.[27]

Table 12-3

AHA/ACC Guidelines for Secondary Prevention for Patients with Coronary and Other Atherosclerotic Vascular Disease[23,25,26]

Risk Factor	Intervention and Goal
Smoking	Complete cessation
	No exposure to environmental tobacco smoke
Blood pressure	<140/90 mm Hg
Lipid management	High intensity statin
Diabetes	Hemoglobin A_{1c} <7%
Physical activity	At least 30 minutes of moderate-intensity aerobic activity (e.g., brisk walking) for minimum of 5 days/week
Weight management	BMI between 18.5 and 24.9 kg/m^2
	Waist circumference, men <40 inches
	Waist circumference, women <35 inches
Influenza vaccination	Patients with CAD should have an annual influenza vaccination

BMI, body mass index; CAD, coronary artery disease; HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol.

ANTIPLATELET THERAPY

Antiplatelet therapy has a central place in the treatment of patients with CAD. Aspirin (acetylsalicylic acid [ASA]) therapy has demonstrated a reduction in the incidence of MI and sudden cardiac death in patients with chronic stable angina. Aspirin's clinical efficacy in chronic stable angina, coupled with its minimal cost and demonstrated efficacy after MI, have made it the gold standard for antiplatelet monotherapy in patients with CAD. Current national guidelines from the American College of Cardiology (ACC)/AHA recommend an ASA dose of 75 to 162 mg daily for the prevention of MI and death. Although higher doses have been investigated in clinical studies, they have not shown increased efficacy, but do increase the risk for adverse effects.[23]

Clopidogrel represents a suitable alternative antiplatelet agent to prevent MI and death in chronic stable angina patients unable to take ASA. The Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events trial (CAPRIE) demonstrated that clopidogrel significantly reduced the incidence of stroke, MI, or vascular death in patients with atherosclerotic vascular disease (previous MI, stroke, or peripheral arterial disease [PAD]) compared with ASA. In addition, clopidogrel was well tolerated with the major adverse effects noted to be gastrointestinal (GI) intolerance and rash. Despite the significant results, the absolute difference in the primary outcome between the two strategies was quite small (0.4%, number need to treat = 200).[30] As such, clopidogrel remains a second-line choice behind ASA in patients with CAD. Clopidogrel should be administered at a dosage of 75 mg/day.

The approach of dual antiplatelet therapy (DAPT), combining ASA with a $P2Y_{12}$ antagonist (clopidogrel, prasugrel, or ticagrelor), has been demonstrated to improve morbidity and mortality in a number of high-risk patients with CVD.[16,17] Given the different mechanisms of antiplatelet effect, combining aspirin with a $P2Y_{12}$ antagonist might be expected to provide additional protection from MI and death in patients with stable CAD as compared to monotherapy. The Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance trial assessed the utility of long-term DAPT in patients with documented CAD or with multiple cardiovascular risk factors. The combination of ASA plus clopidogrel for 28 months did not reduce the risk of death, MI, stroke, or coronary revascularization as compared to ASA alone. However, dual therapy did increase the risk of bleeding.[31]

A post hoc analysis revealed a reduction in ischemic risk in patients with prior MI suggesting that some patients may benefit from long-term DAPT.[31] The Pegasus-TIMI 54 trial evaluated the role of DAPT (low-dose ASA plus either ticagrelor 90 mg BID or 60 mg BID vs. ASA alone) in patients with a prior MI in the previous 1 to 3 years.[32] The median time from MI to randomization was 1.7 years. In over 21,000 patients with a median follow-up of 33 months, ASA plus both doses of ticagrelor reduced the primary end point (cardiovascular death, MI, stroke) compared to ASA monotherapy. This reduction came at the expense of an increased risk of bleeding, with TIMI major bleeding occurring at a rate of 2.6% and 2.3% in the groups receiving ticagrelor 90 mg and 60 mg BID, as compared to 1.06% in patients receiving placebo.[32]

In a separate investigation, patients who received an additional 18 months of DAPT as compared to the standard duration of 12 months in patients who received drug-eluting stents (DES) had a lower rate of stent thrombosis (0.4% vs. 1.4%, $p < 0.001$) and major adverse cardiovascular and cerebrovascular events (4.3% vs. 5.9%, $p < 0.001$), which included a reduction in MI.[33] There was an increase in moderate to severe bleeding (2.5% vs. 1.6%, $p = 0.001$). Up to 40% of the 9,961 patients underwent PCI due to chronic stable angina, and DAPT either consisted of ASA plus clopidogrel, or ASA plus prasugrel.[33]

Given these results, some patients may receive extended durations of DAPT if they have a previous history of prior MI, or are post-PCI and have received a DES.

Anti-Ischemic Pharmacotherapy

Historically, agents used in the treatment of patients with chronic stable angina primarily affected either determinants of myocardial oxygen supply, myocardial oxygen demand, or both. Within this paradigm, β-blockers, CCBs, and chronic nitrate therapy have demonstrated effectiveness in the prevention of ischemic symptoms. In January 2006, the US Food and Drug Administration (FDA) granted approval to ranolazine, representing the first new class of agents to be approved for the treatment of chronic stable angina in the last 20 years. Unlike traditional anti-anginal medications, ranolazine does not affect heart rate or BP. The selection of specific anti-ischemic pharmacotherapy for patients with chronic stable angina should take into account relevant patient characteristics as well as guideline recommendations.

β-BLOCKERS

β-Blockers lower myocardial oxygen demand primarily by lowering heart rate and myocardial contractility. Neither β-selectivity nor the presence of α-1 blockade appear to vary efficacy at preventing ischemia and, therefore, the choice of a specific agent for a given patient will likely depend on cost, number of daily doses, and the presence of other comorbid conditions. β-Blockers with intrinsic sympathomimetic activity are not routinely used in patients with stable angina due to reduced efficacy. The dose of the β-blocker should be titrated to a goal resting heart rate of 55 to 60 beats/minute and therefore will be patient specific.[34] β-Blockers should be avoided in patients with primary vasospastic angina and may worsen symptoms in patients with reactive airway disease or PAD. The most common side effects observed with chronic therapy include bradycardia, hypotension, fatigue, and sexual dysfunction. Other conditions that may prevent the use of β-blocker therapy include severe bradycardia or atrioventricular (AV) nodal conduction defects.[35–37]

NITRATES

Nitrates are available in a number of different formulations and available options are listed in Table 12-4. Regardless of the formulation, all nitrate options are effective at preventing or relieving ischemic symptoms if used appropriately, including the use of a nitrate-free interval. Nitrates can increase myocardial oxygen supply through vasodilation of the coronary arteries, as well as reduce myocardial oxygen demand through the reduction of preload. Nitrates produce vasodilation through the biotransformation and the release of NO.[38] Long-acting nitrates are effective agents for the prevention of anginal symptoms. Sublingual NTG is a vital agent to treat acute anginal attacks. Common side effects of nitrate therapy include hypotension, dizziness, and headache. Headache often will resolve with continued therapy and may be treated with acetaminophen. Concomitant administration with phosphodiesterase type 5 inhibitors (within 24 hours for sildenafil and vardenafil, 48 hours for tadalafil) is contraindicated due to the risk of life-threatening hypotension.[38,39]

CALCIUM-CHANNEL BLOCKERS

CCBs are highly diverse compounds. They differ markedly in chemical structure as well as specificity for cardiac and peripheral tissue. Using these characteristics, it is possible to classify CCBs into several major types (Table 12-5).[40]

Both non-dihydropyridine CCBs (non-DHP CCBs), diltiazem and verapamil, exert similar effects on myocardial and peripheral tissue. They slow conduction and prolong the refractory period in the AV node (see Chapter 15, Cardiac Arrhythmias). Both agents can depress myocardial contractility and are moderate peripheral vasodilators and potent coronary artery vasodilators.[40]

In contrast to diltiazem or verapamil, the dihydropyridines (DHPs) such as nifedipine, amlodipine, felodipine, isradipine, and nicardipine do not slow cardiac conduction. They are more potent peripheral vasodilators and may be associated with a reflex increase in the heart rate. All DHPs have negative inotropic effects in vitro, but these effects, clinically, are overshadowed by the reflex sympathetic activation and decreased afterload. The net effect of these actions results in no or minimal depression of myocardial function (see Chapter 14, Heart Failure).[40]

Both DHP and non-DHP CCBs produce an increase in myocardial oxygen supply through vasodilation of the coronary arteries, as well as reduce myocardial oxygen demand through lowering of intramyocardial wall tension (by lowering systemic BP). However, non-DHP CCBs would be expected to lower myocardial oxygen demand to a greater degree because of additional reductions in heart rate and contractility. Although defined as being within the same pharmacologic class, it is important to consider DHPs and non-DHPs separately when considering their use in patients with chronic stable angina. The reductions in heart rate and contractility with non-DHPs may be beneficial for some patients, although detrimental in others such as patients with compromised left ventricular (LV) function or bradycardia at baseline. Conversely, amlodipine and felodipine have been shown to be safe to use in patients with LV dysfunction and to provide a reasonable option for the prevention of ischemic symptoms in those patients.[40] CCB should be used cautiously when used in combination with cyclosporine, carbamazepine, lithium, amiodarone, and digoxin. Non-DHP CCB should be avoided in most situations due to the duplicate effects on heart rate and cardiac contractility.[1] Side effects of CCB therapy depend on the specific agent used. Use of non-DHP CCBs may result in bradycardia, hypotension, and AV block. Patients receiving DHP CCBs may experience reflex tachycardia, peripheral edema, headache, and hypotension.[40]

RANOLAZINE

Ranolazine is an anti-ischemic agent that inhibits the late sodium current, thereby reducing intracellular sodium. During myocardial ischemia, sodium influx is increased, leading to intracellular calcium overload through the sodium/calcium exchanger. An excess of intracellular calcium leads to changes that promote and worsen ischemia, such as increased intramyocardial wall tension and reduced microvascular perfusion. By inhibiting sodium influx, ranolazine prevents ischemia-induced contractile dysfunction and delays the onset of angina. A key distinction between ranolazine and traditional antianginal agents is that it has no appreciable effect on heart rate and BP. The lack of significant hemodynamic effects makes the drug useful in patients in need of further antianginal therapy but who have low BP or heart rates preventing titration of conventional antianginal agents.[41]

Table 12-4

Commonly Prescribed Organic Nitrates

Drug	Dosage Form	Duration	Onset (minutes)	Usual Dosage
Short-Acting				
NTG	SL	10–30 minutes	1–3	0.4–0.6 mg[a], [b]
NTG	Translingual spray	10–30 minutes	2–4	0.4 mg/metered spray[a], [b]
NTG	IV	3–5 minutes[c]	1–2	Initially 5 mcg/minute. Increase every 3–5 minutes until pain is relieved or hypotension occurs

Long-Acting[d]				
NTG	SR capsule	4–8 hours	30	6.5–9 mg every 8 hours
NTG	Topical ointment[e]	4–8 hours	30	1–2 inches every 4–6 hours[f]
NTG	Transdermal patch	4–>8 hours	30–60	0.1–0.2 mg/h to start; titrate up to 0.8 mg/hour[f]
NTG	Transmucosal	3–6 hours	2–5	1–3 mg every 3–5 hours[f]
ISDN	SL	2–4 hours	2–5	2.5–10 mg every 2–4 hours[f]
	Chewable	2–4 hours	2–5	5–10 mg every 2–4 hours[f]
	Oral	2–6 hours	15–40	10–60 mg every 4–6 hours[f]
	SR capsule	4–8 hours	15–40	40–80 mg every 6–8 hours[f]
ISMN[g]	Tablet (ISMO, Monoket)	7–8 hours	30–60	10–20 mg BID (morning and midday) to start; titrate to 20–40 mg BID[f]
	Extended-release tablet (Imdur)	8–12 hours	30–60	60 mg every day to start; titrate to 30–120 mg every day

[a] When using sublingual or translingual spray forms of NTG, patients should administer the dose while sitting to minimize tachycardia, hypotension, dizziness, headache, and flushing. The optimal dose relieves symptoms with <10- to 15-mm Hg drop in systolic blood pressure or <10-beats/minute rise in pulse. Pain relief is rapid (onset 1–2 minutes; relief in 3–5 minutes), but up to three doses at 5-minute intervals may be given. After this, medical assistance should be summoned.

[b] Sublingual NTG tablets are degraded rapidly by heat, moisture, and light. They should be stored in a cool, dry place; do not leave the lid open or refrigerate. Tablets should be stored in the original manufacturer’s container or a glass vial because the tablets volatilize and bind to many plastic vials and cotton. Previously, stinging of the tongue was an indicator of fresh tablets, but newer formulations only cause stinging in ~75% of patients.

[c] Duration after infusion discontinued.

[d] Longer-acting forms of nitrates are effective drugs, but it is important to understand their limitations to optimize effectiveness. Sublingual ISDN tablets display an onset and duration intermediate between that of sublingual NTG and oral ISDN. Because of high presystemic (first-pass) metabolism of the oral forms of both NTG and ISDN, very large doses may be required compared with SL or chewable dosage forms. Small oral doses (2.5 mg NTG, 5 mg ISDN) are probably not effective; doses as large as 9 mg NTG and 60 mg ISDN are not uncommon. Despite claims for longer activity, ointments and oral forms are often only effective for 4–8 hours, even when given as SR preparations. Also, continued daily use leads to rapid development of tolerance (see note f).

[e] Squeeze 1–2 inches of ointment onto the calibrated paper enclosed in the package with tube. Carefully spread the ointment on chest in a thin layer ~2 inches by 2 inches in size. Keep area covered with applicator paper. Wipe off previous dose before adding new dose or if hypotensive. If another person applies the ointment, avoid contact with fingers or eyes to prevent headache or hypotension.

[f] Dosage regimens should maintain a nitrate-free interval (e.g., bedtime) to decrease tolerance development. Give last oral dose or remove ointment or transdermal patch at 7 PM. Give last dose of SR ISDN in early afternoon.

[g] Major active metabolite of ISDN; 100% bioavailable; no first-pass metabolism, but tolerance may still occur. Rapid-release form (ISMO, Monoket) as 10- and 20-mg tablets. Extended-release form (Imdur) as 60-mg tablets. Okay to cut Indur in half, do not crush or chew.

BID, 2 times daily; ISDN, isosorbide dinitrate; ISMN, isosorbide monohydrate; IV, intravenous; NTG, nitroglycerin; SL, sublingual; SR, sustained-release.

Initial clinical trials demonstrated that ranolazine was an effective agent at reducing anginal episodes when added to existing therapy with CCBs or long-acting nitrates. Subsequent investigations demonstrated long-term safety and efficacy, and the agent may be considered at any stage in the treatment of chronic stable angina. Common adverse effects include headache, constipation, dizziness, and nausea. The drug is extensively metabolized in the liver through both cytochrome P-450 enzymes CYP3A4 and CYP2D6; therefore, attention should be paid to potential drug interactions. CYP3A4 appears to be the major pathway for metabolism and use of ranolazine is contraindicated in patients with significant hepatic dysfunction and in those receiving potent inhibitors and inducers of CYP3A4 such as ketoconazole or rifampin, respectively. Ranolazine is contraindicated in patients receiving many of the available antiretroviral agents.[41]

Myocardial Revascularization

Revascularization of the myocardium, with CABG or PCI, is a mainstay in the treatment of patients with CAD. The goals of revascularization do not differ from the overall goals in treating patients with chronic stable angina, namely, to relieve symptoms, improve quality of life, and prevent MI and death. Historically, a great deal of focus was devoted to comparing CABG, PCI, and medical management and their relative efficacy in relieving symptoms and improving prognosis. In a broad population of patients with CAD, revascularization with either CABG or PCI was found to be superior to medical management therapy alone at relieving symptoms at 1 year, although there was no difference in overall mortality between the treatment strategies.[42] However, CABG therapy tended to be superior at providing long-term relief of symptoms, as well as providing a lower need for repeat revascularization therapy compared to PCI. When considering subgroups of patients with more severe disease or who have manifested left ventricular dysfunction, differences in long-term mortality can be observed among the different treatment strategies. In patients with double-vessel or triple-vessel disease, significant disease of the left main artery, or left ventricular dysfunction, CABG therapy has been demonstrated to provide a reduced 5-year mortality rate compared with PCI or medical therapy alone.[21]

Table 12-5

Calcium-Channel Blockers in Anginal Syndromes

Drug Name	FDA Approved[a]	Usual Dose for Chronic Stable Angina[b]	Product Availability
Dihydropyridines			
Amlodipine	Angina, hypertension	2.5–10 mg every day	2.5, 5, 10 mg tab
Felodipine	Hypertension	5–20 mg every day	5, 10 mg ER tab

Isradapine	Hypertension	2.5–10 mg BID	2.5, 5 mg IR cap
		5–10 mg every day	5, 10 mg CR tab
Nicardipine	Angina (IR only), hypertension	20–40 mg TID	20, 30 mg IR cap
		30–60 mg BID	30, 45, 60 mg SR cap
Nifedipine	Angina, hypertension	10–30 mg TID	10, 20 mg IR cap
		30–180 mg every day	30, 60, 90 mg ER tab
Nisoldipine	Hypertension	20–60 mg every day	10, 20, 30, 40 mg ER tab
Diphenylalkylamines			
Verapamil	Angina, hypertension, SVT	30–120 mg TID/QID	40, 80, 120 mg IR tab
		120–240 mg BID	120, 180, 240 mg SR tab
		120–480 mg every HS	180, 240 mg DR, ER tab
			120, 180, 240, 360 mg ER cap
			100, 200, 300 mg DR, ER tab
Benzothiazepines			
Diltiazem	Angina, hypertension, SVT	30–120 mg TID/QID	30, 60, 90, 120 mg IR tab
		60–180 mg BID	60, 90, 120, 180 mg SR cap
		120–480 mg every day	120, 180, 240, 300, 360 mg cap
			120, 180, 240 mg ER cap
			120, 180, 240, 300, 360, 420 mg ER cap

[a] FDA-approved indications vary among IR and ER products. However, most all have been used clinically for both angina and hypertension. Avoid IR products in hypertension.

[b] Because of short half-lives, most of these drugs are given TID if using IR tabs or caps. Amlodipine has a long half-life and is given once daily.

BID, 2 times a day; cap, capsules; CD, controlled diffusion; CR, controlled-release; DR, delayed-release; ER, extended-release; FDA, US Food and Drug Administration; HS, bedtime; IR, immediate-release; QID, four times a day; SR, sustained-release; SVT, supraventricular including atrial fibrillation, atrial flutter, and re-entry; tab, tablets; TID, three times a day.

Despite the availability of data regarding the relative effects of PCI, CABG, and medical management on morbidity and mortality, there has been a dramatic increase in the use of PCI in recent years. CABG remains the preferred strategy for patients with three-vessel disease or who have multi-vessel disease plus left ventricular dysfunction. In patients with less severe CAD, PCI can be expected to provide similar benefits in mortality as compared to CABG, but may not be as effective at reducing symptoms or the need for repeat revascularization procedures. Recent investigations have indicated that aggressive medical treatment, including intensive lipid-lowering therapy, may be as effective as PCI at improving prognosis over the long term, but may be inferior at reducing symptoms of angina.[1,43,44] These trials are significant in that they highlight the importance of implementing effective strategies, which reduce the progression of CAD, regardless of whether revascularization therapy is utilized. Relevant issues facing pharmacists today not only include optimizing the medical management of CAD but also providing effective pharmacotherapy to prevent complications of PCI.

CLINICAL PRESENTATION OF CHRONIC STABLE ANGINA

CASE 12-1

QUESTION 1: J.P., a 62-year-old dairy farmer, is hospitalized for evaluation of chest pain. About 3 weeks before admission, he noted substernal chest pain brought on by lifting heavy objects or walking uphill. He describes a crushing or viselike pain that never occurs at rest and is not associated with meals, emotional stress, or a particular time of day. When J.P. stops working, the pain subsides in about 5 minutes.

J.P.'s mother and brother died of a heart attack at ages 62 and 57, respectively; his father, who is alive at age 86, has survived one heart attack and one stroke. Family history (except for J.P.) is negative for diabetes mellitus. J.P. is 5 feet 10 inches tall and weighs 235 pounds; he drinks two or three beers a day and does not smoke or chew tobacco.

J.P.'s other medical problems include a 10-year history of hypertension and diabetes for 4 years. Until 3 weeks ago, J.P. could perform all his farm chores without difficulty, including heavy labor. He follows a no-added-salt diet, but consistently eats at fast-food establishments with his favorite meal consisting of two cheeseburgers and French fries.

J.P.'s medication history reveals the following: lisinopril 10 mg once daily, metformin 500 mg BID and hydrochlorothiazide 25 mg once daily. He rarely uses over-the-counter medications. He has an allergy to sulfamethoxazole.

On admission to the cardiac ward, J.P. appears his stated age and is in no apparent distress. Resting vital signs include supine BP, 145/95 mm Hg (last ambulatory visit, 130/85 mm Hg); regular pulse, 84 beats/minute (last ambulatory visit, 78 beats/minute), and respiratory rate, 12 breaths/minute. He has no peripheral edema or neck vein distension, and lung auscultation is within normal limits. Abdominal examination is unremarkable and he is alert and oriented × 3. Cardiac auscultation reveals a regular rate and rhythm with a normal S_1 and S_2; third or fourth heart sounds and murmurs are not noted. A 12-lead ECG reveals normal sinus rhythm at a rate of 84 beats/minute without evidence of previous MI. All intervals are within normal limits.

Admitting laboratory values include the following:

Hct, 43.5%
White blood cell (WBC) count, 5,000/μL
Sodium (Na), 140 mEq/L
Potassium (K), 4.7 mEq/L
Magnesium (Mg), 1.9 mEq/L
Random blood glucose, 132 mg/dL
Hgb A_{1c} 7.4%
Blood urea nitrogen, 27 mg/dL

Serum creatinine, 1.4 mg/dL
Urinary albumin–creatinine ratio, 27 mg/mmol
Chest radiograph is within normal limits.
What signs and symptoms does J.P. exhibit that are consistent with the diagnosis of chronic stable angina?

J.P.'s description of his chest pain includes several common characteristics of angina pectoris (Table 12-2).[1–3] The substernal location of J.P.'s chest pain is typical, although some patients describe pain radiating down the left arm or pain that is referred to the shoulder area or jaw. J.P.'s pain is described as crushing or viselike in quality, which also is common; a fullness in the throat or jaw may occur simultaneously or in lieu of chest pain. In some cases, the patient may not consider these sensations as pain, describing them instead as a sense of pressure or heaviness. Many patients complain of SOB. J.P.'s symptoms are related to exercise and exertion—both known precipitating factors of angina. Most episodes of exertional angina last several minutes in duration and are relieved with rest. Because J.P. has never sought medical attention for his chest pain, his response to NTG cannot be determined.

After getting a detailed description of J.P.'s symptoms, his physician can characterize his chest pain and make a global assessment. Initially, the chest pain should be classified as either typical angina, atypical angina, or noncardiac chest pain. Furthermore, angina should also be classified as either stable or unstable. This distinction is important because it indicates whether his short-term risk of an acute coronary event could be life-threatening. Attempts to categorize J.P.'s anginal symptoms on an objective measurement scale (e.g., Canadian Cardiovascular Society Grading Scale) can be misleading.[45] For example, a sedentary 65-year-old patient's class II symptoms may be tolerable, but the same symptoms could significantly disable an active 50-year-old patient.

J.P.'s chest pain is of a quality and duration characteristic of angina, provoked by exertion, and relieved by rest; therefore, J.P.'s constellation of symptoms can be classified as typical chest pain. J.P.'s symptoms do not occur at rest; however, they should be classified as stable angina.[1–3]

CASE 12-1, QUESTION 2: Assess J.P.'s physical examination. What signs and symptoms are relevant to the angina?

The physical examination typically provides little information about the presence of CAD. The most useful findings pertain to the cardiovascular system where heart rate and BP can be increased during an acute anginal episode. J.P.'s physical examination is characteristic of a man of his age with angina.[3] He is obese and hypertensive, but his cardiac examination is normal. The presence of murmurs would have required further workup; the absence of a third heart sound suggests that the left ventricle may be functioning normally. (See Chapter 14, Heart Failure, for a description of third heart sounds.) The absence of a fourth heart sound in J.P. is indicative of a low probability of cardiac end-organ damage resulting from systemic hypertension. His chest radiograph, which is normal, does not present evidence of other complications commonly associated with myocardial ischemia (e.g., enlarged heart, HF).

J.P.'s physical examination should also evaluate the possibility of the presence of atherosclerosis in other major vascular beds (peripheral vascular disease, cerebrovascular disease, abdominal aortic aneurysm). The presence of xanthomas would suggest severe hypercholesterolemia, but these were not noted in J.P.

Diagnostic Procedures

CASE 12-1, QUESTION 3: What other objective diagnostic procedures are helpful to confirm CAD and angina in J.P?

A 12-lead ECG indicates there is no ongoing ischemia at this time. As such, it does not help confirm the diagnosis of CAD. An echocardiogram could be used to better assess cardiac structure and function, including ruling out other potential causes for myocardial ischemia such as valvular dysfunction or pericardial disease, but would not definitively confirm the presence of CAD. Electron bean computed tomography or CCTA could be used to detect the presence of coronary atherosclerosis, but in J.P. would not offer vital prognostic information available with other testing modalities.[1]

Given J.P's current lifestyle and activity level, he would likely be able to tolerate exercise treadmill testing. Treadmill testing would be an appropriate initial diagnostic modality in J.P. due to its noninvasive nature, reliability with established protocols, as well as the ability to offer prognostic information regarding the risk of MI and death for J.P. Therefore stress testing, in this case with exercise treadmill versus pharmacologic means, is an excellent initial diagnostic modality to use in J.P.

CASE 12-1, QUESTION 4: Should J.P. undergo cardiac catheterization? How will the results of this invasive procedure influence future therapy?

Coronary catheterization and angiography is the best test for the definitive diagnosis of CAD. In addition, angiography is the most accurate means of identifying less common causes of chronic stable angina, such as coronary artery spasm.[1]

Although angiography is effective at identifying flow-limiting atherosclerotic plaques in the coronary vasculature, it cannot provide information on whether those lesions are causing clinical symptoms. Stress testing is often a more appropriate initial modality to first characterize the myocardial ischemia that takes place with exertion. Patients with significant ischemia via stress testing should then undergo cardiac catheterization to determine the nature and extent of disease. The results of angiography will be useful in determining the risk of death or MI in J.P. and, subsequently, the course of needed treatment. For example, patients who have a significant stenosis in the left main coronary artery are at high risk of death and should undergo CABG.[20]

Risk Stratification and Prognosis

CASE 12-1, QUESTION 5: After having a positive treadmill stress test and undergoing subsequent cardiac catheterization, J.P. is found to have two-vessel CAD with obstructive lesions of 55% and 70% in the right coronary artery (RCA) and circumflex arteries, respectively; the LAD coronary artery is not involved. What is his prognosis?

The prognosis of patients with stable angina is variable and dependent on the presence of other factors and comorbid conditions. The extent of CAD, quantification of ventricular function, the response to stress testing, as well as the initial clinical evaluation all help to provide an estimate of risk in a given patient. Developing a level of risk for a particular patient helps determine the appropriate treatment strategy.[1,2]

J.P.'s history and physical examination suggest he does not have HF; poor LV function would be an ominous concurrent finding. J.P. also does not have three-vessel disease or blockage of the LAD artery. J.P. does have type 2 diabetes, which elevates his risk for future cardiovascular events. The absence of other major comorbid conditions, myocardial dysfunction, along with the current extent of CAD indicates that J.P.'s prognosis at this time is favorable provided he initiate appropriate treatment strategies demonstrated to reduce morbidity and mortality in patients with CAD.[1,2]

Medical Management of Chronic Stable Angina

CASE 12-1, QUESTION 6: How should J.P. be managed at this time? Should he undergo revascularization with PCI or CABG, or be managed medically?

As discussed previously, goals for managing CAD and angina in J.P. include relief of symptoms and reduction of myocardial ischemia to improve quality of life, as well as prevention of major complications of CAD such as acute MI and death.[1] Depending on the patient, both goals may be accomplished through surgical revascularization, medical management, or both. Regardless of the treatment strategy chosen to relieve ischemic symptoms, therapies that prevent death (vasculoprotective agents) should receive priority.

Presently, CABG is not the best option for J.P. because the usual indications for surgical therapy include presence of left main CAD, presence of three-vessel disease (especially if LV function is impaired), or ineffectiveness of medical therapy.[1,20]

However, revascularization with PCI is a potential option along with medical management alone. Although PCI would offer no mortality advantage over medical therapy at this time, it has been shown to decrease the incidence of recurrent symptoms in the short term (1 year).[1] If J.P. can implement aggressive lifestyle modifications and control of risk factors, progression of CAD and control of ischemic symptoms will be similar to PCI within a 5-year time frame.[42] Both strategies, including the pros and cons of PCI or medical management alone, should be offered to J.P. so that an informed decision can be made in accord with his wishes. Overall, J.P. will probably do well with medical therapy. His life expectancy depends on progression of the disease and development of other complications of CHD (HF, MI, sudden cardiac death).

RISK FACTORS AND LIFESTYLE MODIFICATIONS

CASE 12-1, QUESTION 7: What independent risk factors for CAD are present in J.P.? Which of these may be altered?

The first step in the treatment of any patient with chronic stable angina or CAD should be the modification of any existing risk factors and the adoption of a healthy lifestyle. By addressing the underlying circumstances, which likely led to the development of CAD, a significant impact can be made at halting the progression of the disease and preventing complications of CAD. Current recommendations for the goals for risk factor management are listed in Table 12-3.[23,25,26] In addition to specific risk factor goals, attention should be paid to evidence that favors specific drug therapies that have evidence supporting reductions in morbidity and mortality. Examples would include the use of HMG-CoA reductase inhibitors in the treatment of hyperlipidemia,[1,2] as well as the use of ACE inhibitors for the treatment of hypertension.[25,26]

J.P. has several risk factors for CAD, some of which cannot be altered, such as middle age, male sex, and a strong family history of CAD. Risk factors, such as hypertension, obesity, hypercholesterolemia, smoking, and possibly stress, can potentially be modified to decrease the likelihood of adverse sequelae for J.P. His hypertension should be controlled and statin therapy should be initiated (see Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease). A fasting Hgb A_{1c} should be drawn with a goal of less than 7% (see Chapter 53, Diabetes Mellitus). Dietary modification and weight reduction for J.P. are mandatory, because they positively influence several risk factors. J.P., however, does not smoke cigarettes, which would significantly increase his cardiovascular risk.[1,22] J.P.'s active lifestyle may influence his prognosis favorably.[1]

DIETARY INTERVENTIONS

CASE 12-1, QUESTION 8: Are there any dietary patterns that J.P. can adopt that have demonstrated reductions in cardiovascular end points?

Although the positive effects of lifestyle modifications on cardiovascular risk factors are well recognized, the effect of specific lifestyle interventions on reducing hard cardiovascular end points can be underappreciated. The adoption of a healthy dietary pattern is one such example. Randomized controlled trials have demonstrated that the adoption of the Mediterranean Diet (diets emphasizing whole grains, fruit, vegetables, nuts and legumes, moderate dairy intake, moderate amounts of lean protein, and polyunsaturated fats) reduced the relative risk of MI or cardiac death by 50% to 73% as compared to a diet similar in composition to the AHA Step I diet.[46] It is important to note that in one of these studies, the Lyon Diet Heart Study, the improvements in cardiovascular morbidity and mortality occurred without significant changes in the lipid profiles of study subjects.[46] One trial found the Mediterranean Diet supplemented with either nuts or olive oil reduced cardiovascular events in patients at high risk of CVD when compared to a low fat diet.[47] Several additional trials demonstrated that patients with a history of MI who increased their intake of either fatty fish or ingested omega-3 fatty acid fish oil supplements also had reductions in cardiovascular death and

---

MI as compared to control patients without dietary intervention.[48] Lastly, epidemiologic studies have confirmed the results from randomized controlled trials showing that adherence to a Mediterranean diet significantly reduces cardiovascular morbidity and mortality.[46] A Mediterranean diet reduces systemic inflammation as measured by C-reactive protein, reduces the incidence of insulin resistance, and improves endothelial function. Although a great deal of attention has been directed at the increased intake of omega-3 polyunsaturated acids (eicosapentaenoic acid and docosahexaenoic acid derived from fish or α-linoleic acid derived from plants) being responsible for the observed benefits in each of these trials, multiple dietary alterations were likely in play. The results should be interpreted as the result of the adoption of a healthy dietary pattern.[22]

CASE 12-1, QUESTION 9: J.P. states he had heard that antioxidants such as vitamin E could benefit him along with a daily B vitamin. Would these supplements offer significant cardiovascular benefit for J.P.?

Because oxidation of LDL in the arterial wall is a key step in the atherosclerotic process, considerable interest exists in the theory that supplementation with high doses of antioxidants such as vitamin E, vitamin C, and β-carotene might mitigate this process and slow the progression of atherosclerosis. Early observational studies of antioxidants seemed to confirm this theory. Multiple large randomized studies, however, have shown no positive effect from supplemental intake of antioxidants such as vitamin E on the incidence of cardiovascular outcomes including MI or death.[1,49] These findings were observed in both primary and secondary prevention of cardiovascular events. J.P. should be informed that supplemental intake of vitamin E will not have any positive effect on his CVD.

Interest in the use of supplemental intake of folic acid and B vitamins stems from their ability to lower homocysteine levels. It is well established that elevated levels of homocysteine are associated with a higher incidence of CVD.[50] Despite this association, the great majority of appropriately designed, randomized, placebo-controlled studies have demonstrated that supplemental ingestion of folic acid and B vitamins has no impact in reducing cardiovascular outcomes such as MI or death[1,51] Therefore, similar to the advice for vitamin E, J.P. should be counseled that folic acid and B vitamin supplementation will not provide any tangible cardiovascular benefit.

Anti-Ischemic Drug Therapy

SUBLINGUAL NITROGLYCERIN

CASE 12-1, QUESTION 10: Should J.P. receive a prescription for SL NTG on discharge from the hospital? If so, what education should J.P. receive with regard to the use and storage of SL NTG?

All patients with CAD, especially those with chronic stable angina, should receive a prescription for SL NTG for the treatment of acute anginal attacks.[38,39] NTG leads to vasodilation of both veins and arteries which reduces myocardial oxygen demand, thereby relieving angina. Because response to NTG varies among patients, the dosage should be individualized (Table 12-4). Most patients, however, use a dose of 0.4 mg. The administration of sublingual NTG is also useful in patients who have a good understanding of what level of exertion produces their chest pain. About 5 to 10 minutes before J.P. is about to undergo heavy exertion, he can take a sublingual NTG tablet to prevent angina.[1]

Patient education is a crucial component of ensuring SL NTG is used appropriately to treat acute anginal attacks. When angina occurs, J.P. should sit down immediately and utilize his SL NTG. If using tablets, he should place the NTG tablet under his tongue; he should not swallow it. If using the NTG spray, he should apply the spray on or under the tongue and not swallow or inhale it. Many patients experience dizziness and light-headedness, which is minimized by sitting. The onset of action is within 1 to 2 minutes, and pain usually is relieved within 3 to 5 minutes. If the pain persists or is unimproved 5 minutes after the first dose of NTG, the patient should call 9-1-1 as they may be experiencing an MI.[1] If he needs more than one dose, he can take a maximum of 1.2 mg in 15 minutes.

The tablets should be dispensed in the original, unopened manufacturer’s container and stored in the original brown bottle. Because sublingual NTG tablets are degraded by heat, moisture, and light, they should be stored in a cool, dry place, but not refrigerated. The bottle should be closed tightly after each opening. Safety caps should not be used, although patients should be cautioned to keep all medications out of the reach of children. The cotton plug sometimes is difficult to remove. Therefore, it should be discarded on initial receipt of the prescription and should not be replaced. Use of cotton other than that supplied by the manufacturer should be discouraged because NTG tablets are volatile and are adsorbed by household cotton. This results in a significant loss in tablet effectiveness. Expiration dating should be monitored closely, and tablets should be replaced immediately if they are exposed to excessive light, heat, moisture, or air. Once a container is opened, the tablets should be used for only a limited time—usually from 6 months to 1 year.[1]

ADRENERGIC BLOCKERS

CASE 12-1, QUESTION 11: Given J.P.'s active lifestyle and recent history of frequent anginal attacks, the medical team wishes to optimize chronic preventative therapy for chronic stable angina. J.P. currently is receiving metformin 500 mg BID, lisinopril 10 mg once daily, and hydrochlorothiazide 25 mg once daily. His current resting heart rate and BP are 78 beats/minute and 135/90 mm Hg, respectively. Is a β-blocker the best initial option for chronic stable angina in J.P.?

Options for chronic prevention of anginal episodes include β-blockers, CCBs, long-acting nitrates, and ranolazine. Although each of these options is considered relatively equivalent in terms of ischemia prevention, current guidelines recommend that β-blockers should be administered before a nitrate or a CCB when long-term therapy is indicated.[1,2] β-Blockers are very effective at reducing anginal symptoms and ischemia, including silent myocardial ischemia.[1,2] β-Blockers also significantly increase exercise tolerance and time to ST-segment depression during exercise testing.[36] Several cohort and case–control studies have shown that β-blockers improve clinical outcomes, including reductions in mortality in patients with chronic stable angina or CAD.[52–56] In addition, recent evidence indicates that β-blockers may also slow the progression of atherosclerosis.[57] In a meta-analysis of clinical trials that compared the three classes of anti-ischemics, no differences in long-term mortality were noted. β-Blockers, however, were more effective in lowering the incidence of anginal episodes.[58] β-Blockers are generally considered the most effective class of agents at preventing silent myocardial ischemia.[3] In addition, β-blockers clearly lower morbidity and mortality in patients with CAD[17,19] and HF.[36] Overall, the body of literature available supports the recommendation that all patients with angina should receive a β-blocker as initial therapy unless contraindicated.[59] J.P. at this time does not appear to have any contraindications to β-blocker therapy, and β-blocker therapy should be initiated.

CASE 12-1, QUESTION 12: How should therapy with a β-blocker be optimized in J.P.?

All patients receiving antianginal drugs should be monitored for frequency of angina attacks and SL NTG consumption. Traditionally, clinicians have monitored the reduction in resting heart rate and have progressively increased the β-blocker dose until the resting heart rate was 55 or 60 beats/minute.[36] J.P. currently has a heart rate of 78 beats/minute and preserved BP. If J.P. continues to have preserved BP and his heart rate remains above 55 to 60 beats/minute after the initiation of β-blocker therapy, a doubling of his dose would be a reasonable increase, with close monitoring of heart rate and BP. Additional goals with β-blocker therapy include a maximum heart rate of 100 beats/minute or less with exercise. Resting heart rate less than 50 beats/minute may be acceptable, provided the patient is asymptomatic and heart block is not present. Variations in resting heart rate are normal and subject to the influence of the endogenous sympathetic nervous system and other exogenous factors, such as drugs, tobacco, and caffeine-containing beverages. β-Blockers with intrinsic sympathomimetic activity (e.g., pindolol) will not reduce the resting heart rate as much as β-blockers lacking this activity.[35]

Exercise stress testing is probably the most accurate, but least practical, method of documenting the adequacy of β-blocker therapy. During an exercise tolerance test, a β-blocker should substantially increase the time J.P. walks before developing angina. There also may be a reduction in ST-segment depression during exercise, indicating less myocardial ischemia. The rate–pressure product probably will be markedly lower, reflecting a decrease in both heart rate and systolic wall tension.[34] An alternative to conducting a formal stress test is to repeat the physical activity which produced angina during this hospitalization, namely, walking a few flights of stairs.

CASE 12-1, QUESTION 13: Would the decision to use β-blockers initially in J.P. be altered if he had a history of reactive airway disease such as asthma or PAD?

Although all β-blockers are equally effective in the treatment of angina, the addition of reactive airway disease or PAD to J.P.'s medical history would pose several relative contraindications to the use of some β-blockers. The concern directly relates to the potential for β-blockers to worsen either bronchoconstriction in the case of asthma by blunting β_2 receptors, or worsening vasoconstriction in the peripheral arteries, again, through blunting vasodilation through β_2 receptors. Although not absolute contraindications, the presence of these disease states warrants careful monitoring of β-blocker therapy during initiation and titration.[34]

Cardioselective β-blockers, such as metoprolol, are often considered in patients with reactive airway disease or PAD with the hope that β_2 receptors will be unaffected. In one meta-analysis, cardioselective β-blockers were better tolerated than nonselective β-blockers in patients with asthma.[60] Cardioselective β-blockers also are less likely to inhibit β_2-mediated vasodilation in the peripheral arterioles. Therefore, cardioselective β-blockers are preferred over nonselective β-blockers for patients with PAD and Raynaud disease.[61]

Unfortunately, cardioselectivity is not an all-or-none response; instead, it is a dose-dependent phenomenon. As the dose is increased, cardioselectivity is lost. The dose at which cardioselectivity will be lost in any given patient cannot be predicted, and even a very small dose (e.g., metoprolol 50–100 mg) could cause wheezing.[35,61] If β-blocker therapy is to be initiated in a patient with reactive airway disease or PAD, close monitoring for worsening of symptoms should occur and an alternative anti-ischemic medication should be used if symptoms worsen.

In the event that β-blocker therapy is not tolerated or considered too risky, initial therapy with a heart-rate–controlling CCB is the next best option, provided there is adequate heart rate and BP to tolerate therapy. In patients who already have low heart rate and/or marginal BP, ranolazine may be considered as an initial option. Long-acting nitrates are typically reserved for add-on therapy for reasons that will be subsequently discussed.[1]

CASE 12-1, QUESTION 14: J.P. is being discharged from the hospital today with prescriptions for SL NTG 0.4 mg tablets, metoprolol succinate 100 mg once daily, metformin 500 mg BID, and lisinopril 20 mg once daily, and education regarding diet and exercise. Is there anything else J.P. should receive for his chronic stable angina?

Antiplatelet therapy is a cornerstone in the management of a patient with atherosclerotic vascular disease. Antiplatelet therapy reduces the incidence of CVD events such as MI, stroke, and death. Although newer antiplatelet options are available, aspirin is still the first-line choice for patients with atherosclerotic vascular disease due to well-established efficacy and cost-effectiveness.[1]

The mechanism of action for aspirin's antiplatelet effect is inhibition of cyclooxygenase (see Chapter 11, Thrombosis). By acetylating the active site of cyclooxygenase, aspirin blocks the formation of prostaglandin endoperoxides from arachidonic acid. This inhibits the formation of both thromboxane and prostacyclin. Thromboxane A_2 is a potent vasoconstrictor and facilitates further activation of platelets. Prostacyclin (PGI_2) counterbalances the effect of thromboxane A_2, because it is a potent inhibitor of platelet aggregation and a vasodilator.[62]

Although it has been theorized that higher doses of aspirin would produce a higher level of efficacy than low doses, all available literature indicates that low dosages of aspirin (75–325 mg/day) are as effective as higher dosages (625–1,300 mg/day) in the treatment of patients with angina.[62] Conversely, as the aspirin dosage increases, the incidence of adverse effects, especially GI bleeding, increases. Therefore, current guidelines recommend a daily dosage of 75 to 162 mg orally for the prevention of MI and death in patients with CAD.[1] Given this information, J.P. should be advised to take aspirin at a dose of 81 mg/day to maintain efficacy but decrease the risk of adverse effects.

CASE 12-1, QUESTION 15: J.P. returns to the hospital with recurrent angina 8 weeks after he was discharged. He mentioned he stopped his metoprolol 36 hours ago when he forgot to get his prescriptions refilled. He is transported to the hospital emergency department for treatment of angina unresponsive to 3 NTG tablets. How could J.P.'s situation have been avoided?

The β-blocker withdrawal syndrome is a rebound phenomenon resulting from heightened β-receptor density and sensitivity (i.e., upregulation) subsequent to receptor blockade. It places patients with CAD at high risk for adverse cardiovascular events, which may include acute MI and sudden cardiac death. An "overshoot" in heart rate, as a consequence of sympathoadrenal activity from abrupt β-blocker withdrawal increases myocardial oxygen demand and platelet aggregation. Withdrawal syndromes may be less severe in patients taking β-blockers with partial agonist activity.[34–36]

If β-blockers are to be discontinued, a gradual tapering schedule (preferably for 1–2 weeks) should be used. Shorter periods for β-blocker withdrawal (e.g., 2–3 days) have been proposed, although the optimal strategy for discontinuation is not known. Ensuring that β-blockers are tapered and that the patient is reasonably monitored for adverse events for the duration of the taper is imperative. Patients should limit physical activity throughout the β-blocker withdrawal period and seek prompt medical attention when angina symptoms become apparent. Patients should be

---

warned not to precipitously discontinue their β-blockers. Failure to renew prescriptions and financial hardship are common reasons for abrupt discontinuation, and clinicians need to have sufficient professional rapport with patients to understand when patients encounter difficulties in obtaining medications.

LONG-ACTING NITRATES

CASE 12-1, QUESTION 16: J.P. recovers quickly and is discharged from the hospital after 48 hours. He does well during the next several months, but he is still bothered by occasional angina episodes, two to four times a week. The attacks usually are precipitated by strenuous work and are relieved by rest and two or three NTG tablets. The quality and location of the pain are unchanged, although the duration has increased by 1 or 2 minutes. He follows a low-cholesterol, no-added-salt diet.

Physical examination is unchanged except for a 20-lb weight loss. Vital signs include the following: supine BP, 119/76 mm Hg; heart rate, 60 beats/minute; and respiratory rate, 12 breaths/minute. J.P.'s cardiologist elected to start a long-acting prophylactic nitrate (isosorbide mononitrate) as well as continuing his metoprolol succinate (100 mg daily), lisinopril (20 mg daily), aspirin (81 mg daily), and metformin (500 mg twice daily). Is a long-acting nitrate the best add-on option for J.P.'s chronic stable angina?

Long-acting nitrates occupy a key role in the prevention of angina of all types. The goals of therapy are to decrease the number, severity, and duration of J.P.'s anginal attacks. A CCB could be prescribed for J.P. instead of isosorbide mononitrate because he has no contraindications to this class of drugs. A CCB would have been a good alternative if his BP had remained elevated, but for now, J.P.'s BP and pulse are within a desired range. Nitrates can also affect BP, but will likely do so to a lesser extent than CCBs. Because sublingual nitrates were well tolerated by J.P., a long-acting nitrate would be acceptable. If a CCB is considered at this point, a DHP should be used because they have no effect on heart rate, unlike diltiazem or verapamil. Lastly, ranolazine would be an option for add-on therapy, especially if J.P. experiences any adverse hemodynamic effects from either a CCB or long-acting nitrate. Ultimately, the decision for additional therapy is based on the prescriber's personal choice and past experience, as well as the entire spectrum of the patient's disease complex.[63]

CASE 12-1, QUESTION 17: Will J.P. develop tolerance to the long-acting nitrate?

Although not completely understood, several mechanisms of nitrate tolerance have been proposed, including the increased production of catecholamines, plasma volume expansion, and activation of the renin-angiotensin-aldosterone system.[64]

All organic nitrates exhibit similar hemodynamic effects through a common pharmacologic mechanism; yet, the differing pharmacokinetic profiles of the nitrate delivery systems lead to a variation in the development of tolerance.[65] Short-acting formulations (e.g., SL NTG, oral NTG spray, and SL isosorbide dinitrate) are not likely to induce tolerance given their rapid onset of action and short duration of effect. Oral nitrates and transdermal products, both having an extended duration of action, are likely to induce tolerance.

Intermittent application of transdermal NTG can limit tolerance development in patients with both chronic stable angina and HF. The effects of continuous (24 hours/day) and intermittent (16 hours/day) transdermal NTG (10 mg/day) were compared in 12 men with chronic stable angina who also were being treated with β-blockers or CCB.[66] Nitrate efficacy was maintained with intermittent treatment and an 8-hour nitrate-free interval. Tolerance to the antianginal effects occurred, however, with continuous treatment. Twelve-hour intermittent patch therapy also prevents tolerance.[67] The minimal time necessary for a nitrate-free interval is unknown. Nitrate dosing schedules should be arranged to permit a nitrate-free interval during which time the patient may receive angina protection from β-blockers, CCBs, or ranolazine. Most often, this nitrate-free interval is arranged during the night because angina is more likely to occur during the workday. Patients with nocturnal or early morning angina should arrange their nitrate-free interval during the day.[68]

Despite the availability of nitrate preparations that can be dosed once or twice a day (isosorbide mononitrate), oral isosorbide dinitrate is still commonly used in a variety of settings for the treatment of angina. Isosorbide dinitrate needs to be dosed three times a day, and presents a challenge in ensuring patients have a nitrate-free interval. If J.P. were to receive isosorbide dinitrate, he should take his oral nitrate at 7 AM, noon, and 5 PM because his exercise-induced angina is likely to occur during daylight hours. If he were to take isosorbide dinitrate on a more traditional three-times-a-day or every-8-hours schedule, he would be in danger of not having an adequate nitrate-free interval. Because long-acting nitrates must be dosed intermittently to avoid tolerance, metoprolol therapy will provide J.P. with continuous protection, even during the nitrate-free interval. Although J.P. uses a long-acting nitrate, he still will respond favorably to sublingual NTG. No evidence indicates that use of long-acting nitrates leads to resistance or tolerance to the effects of sublingual NTG.

CASE 12-1, QUESTION 18: Does isosorbide mononitrate offer any distinct advantages over other nitrate preparations for angina prophylaxis?

Isosorbide mononitrate is the primary metabolite of isosorbide dinitrate. In fact, most of the clinical activity of isosorbide dinitrate is due to the mononitrate. Therefore, both drugs share a similar pharmacology. Isosorbide mononitrate does not undergo first-pass metabolism and has no active metabolites. Its oral bioavailability is almost 100%, and its overall elimination half-life is about 5 hours.[65] Maximal serum concentrations are observed 30 to 60 minutes after a dose. To minimize the potential development of nitrate tolerance, isosorbide mononitrate should be used in a twice-daily, asymmetric dosing regimen in which the first dose is taken on awakening and the second dose about 7 hours later. Because of this unconventional dosing pattern and the availability of the extended-release product, which can be taken once a day, most use of isosorbide mononitrate is in the form of the extended-release preparation. Pharmacists must be sure to recognize the difference between these two products.

General precautions and adverse reactions for isosorbide mononitrate are similar to those for the other nitrates. Potential advantages for the clinical use of isosorbide mononitrate are less dosage fluctuation because of the absence of presystemic clearance and an effective once-daily or twice-daily dosing schedule, which could perhaps lead to improved patient adherence. Nevertheless, isosorbide dinitrate is effective clinically when administered two or three times a day and is a viable alternative.

CASE 12-1, QUESTION 19: J.P. likes the idea of using topical nitrates instead of an oral agent. Are the transdermal patches a viable alternative?

Transdermal NTG patches were originally designed to provide anti-ischemic protection with once-daily application. The concept of a compact, easy-to-apply transdermal NTG patch prompted pharmaceutical manufacturers to design a number of products, which the FDA subsequently approved based on plasma level data, not clinical efficacy studies. Subsequently, the shortcomings of plasma level data have become apparent and prompted numerous clinical efficacy studies.

Transdermal NTG therapy has been shown to increase exercise duration and maintain an anti-ischemic effect for 12 hours after patch application. These beneficial responses remained consistent throughout 30 days of therapy. No significant nitrate tolerance or rebound was noted when the patch was applied for not more than 12 of 24 hours.[65]

Although the various patches use different pharmaceutical delivery systems, clear-cut advantages of one over another are not apparent. Despite variations in surface area and NTG content, the most important common denominator of the transdermal NTG systems is the amount of drug released per hour expressed as the release rate (e.g., 0.2 mg/hour). Each product label includes this information. Low dosages (0.2–0.4 mg/hour) may not produce sufficient plasma and tissue concentrations to produce a clinically significant effect[3]; however, it is still recommended to start with a low-dose patch and titrate upward as needed. Because the skin is the major factor influencing NTG absorption rate, product release characteristics do not favor one system over another. Contact dermatitis has been reported with the transdermal patches. Patient instructions are included with the patches and should be reviewed with the patient, emphasizing the appropriate time for application of the patch, removal of the patch, as well as the appropriate sites on the body where the patch should be placed.

CALCIUM-CHANNEL BLOCKERS

CASE 12-2

QUESTION 1: B.N., a 56-year-old man, has just undergone cardiac catheterization, which showed two-vessel CAD with obstructions of 55% and 65% in the right coronary and circumflex coronary arteries, respectively. Before catheterization he had a 2- to 3-month history of exertional angina for which his primary care physician prescribed sublingual NTG tablets (0.4 mg) and oral isosorbide mononitrate (60 mg once daily). B.N. discontinued the use of isosorbide mononitrate after a few weeks due to intolerable headaches. His medical history includes asthma, hypertension, and hyperlipidemia. Currently, his other medications include losartan 100 mg once daily, fluticasone inhaler two puffs twice daily, albuterol inhaler two puffs as needed, aspirin 81 mg daily, and atorvastatin 20 mg daily. Current vital signs include a resting heart rate of 75 beats/minute, BP of 125/80 mm Hg, and respiratory rate of 14 breaths/minute. His physician begins antianginal therapy with oral diltiazem 120 mg once daily. Is this a good option for B.N. and his chronic stable angina?

CCBs are effective in both vasospastic and classic exertional angina. These drugs relieve vasospasm of the large coronary arteries and, as a result, are effective in treating Prinzmetal variant angina. Their beneficial effect in chronic stable (effort-induced) angina is the result of multiple factors. Their vasodilatory effects in the coronary circulation increase myocardial oxygen supply, whereas dilation of the peripheral arterioles leads to a reduction in myocardial oxygen demand. Because coronary vasospasm can occur at the site of an atherosclerotic plaque, a CCB is particularly useful in patients who have a vasospastic component to their angina.[40,69]

Although β-blockers are considered the drugs of choice when instituting antianginal therapy[1], data indicate that the selection of a heart rate–lowering CCB may also be a reasonable first-line choice. CCBs and β-blockers appear to provide equivalent efficacy in head-to-head trials of chronic stable angina.[70,71] In addition, the available head-to-head trials with sufficient numbers also suggest that CCBs and β-blockers produce similar effects on cardiovascular outcomes and mortality in patients with chronic stable angina.[72,73] In addition, several trials in the setting of hypertension with CAD have demonstrated that CCBs can produce meaningful reductions in mortality.[74–77] It would appear that either a heart rate–lowering CCB, or a β-blocker, may be considered relatively equal options and initial therapy for chronic stable angina. The selection of a particular class will likely be dictated by patient characteristics.

In the case of B.N., his asthma may be worsened by the addition of a β-blocker. Although a cardioselective β-blocker could be tried to see if B.N. could tolerate it, a heart rate–lowering CCB is a good alternative to a β-blocker for the treatment of angina in this situation. The choice of a CCB as initial therapy in this patient is appropriate due to B.N.'s previous intolerance to nitrates and because nitrate therapy requires a nitrate-free period.[1]

Given B.N.'s current heart rate and BP, the selection of a heart rate–lowering CCB seems most appropriate. However, the distinct pharmacologic and adverse event profiles of the various classes may dictate agent selection from patient to patient. Some side effects of CCBs reflect an extension of their hemodynamic and electrophysiologic profiles and, therefore, are predictable (Table 12-6). DHP-induced hypotension and dizziness occur in approximately 15% of patients. Patients also may complain of light-headedness, facial flushing, headache, and nausea. Swelling of the lower legs and ankles (peripheral edema) is related to the potent peripheral vasodilating effects of these agents. The non-DHPs, verapamil and diltiazem, have similar side effect profiles, although diltiazem appears to be better tolerated. The lower incidence of side effects reported with diltiazem, compared with verapamil, may reflect a true difference or, perhaps, less aggressive dosing regimens. Both drugs can cause sinus bradycardia and worsen already existing conduction defects and heart block.[40,69] Neither should be used in patients with sick sinus syndrome or advanced degrees of heart block unless a functioning ventricular pacemaker is present. Patients should be monitored for signs of worsening HF, such as SOB, weight gain, and peripheral edema. Verapamil-induced constipation can be particularly troublesome to the elderly.[40,64]

Appreciation for the individual side effect profiles helps determine preference for one CCB over another. B.N. is not likely to experience major side effects with either verapamil or diltiazem.

CASE 12-2, QUESTION 2: On questioning, B.N. does not report any previous adverse events or tolerance issues with an ACE inhibitor. Is an ARB appropriate to use in B.N, or should he be switched to an ACE inhibitor for his CAD?

As discussed previously, the totality of available evidence supports the role of ACE inhibitors in reducing total mortality, cardiovascular mortality, nonfatal MI, and stroke in patients with stable IHD and preserved ventricular function. Although in theory ARBs should produce the same beneficial effects as ACE inhibitors in patients with atherosclerosis, there are far fewer clinical trials with ARBs. The best supporting evidence comes from the TRANSCEND and ONTARGET trials, both of which suggest ARBs produce similar benefits as ACE inhibitors in preventing CVD events.[78,79] Based on these trials, it would be reasonable to continue ARB therapy in B.N. at this time given he has demonstrated the ability to tolerate the medication. It would not be unreasonable though to discuss with B.N. the possibility of switching to an ACE inhibitor given the substantial body of evidence that exists for patients with CAD. The combination of an ACE inhibitor and ARB does not offer any increased benefit but does increase the risk of hyperkalemia and renal insufficiency.[79]

Table 12-6

Calcium-Channel Blocker Hemodynamic and Electrophysiologic Profile[40,69]

Effect	Dihydropyridine Derivatives[a]	Diltiazem	Verapamil
Peripheral vasodilation[b]	+++	++	++
Coronary vasodilation[b]	+++	+++	++
Negative inotropes[c]	±	++	+++
AV node suppression[c]	±	+	++
Heart rate	Increase (reflex)	Decrease or unchanged	Decrease or unchanged
Pharmacokinetics[d]			
Dosing[e]			
Side Effects			
Nausea, vomiting	+ (most)	+/1	±
Constipation	Not observed	±	+
Hypotension, dizziness[f]	++	+	+
Flushing, headache	++	+	+
Bradycardia, HF symptoms	±	+	++
Reflex tachycardia, angina	+[f]	Not observed	Not observed
Peripheral edema	+	±	±

[a] Dihydropyridine derivatives that are US Food and Drug Administration approved for angina: amlodipine (Norvasc), nicardipine (Cardene), and nifedipine (Adalat, Procardia).

[b] Peripheral and coronary vasodilation helpful for angina, hypertension, and possibly HF, but peripheral dilation is the basis for side effects of flushing, headache, and hypotension.

[c] AV node suppression is helpful for controlling supraventricular arrhythmias, but this property plus the negative inotropic effect may worsen HF. Nifedipine has less negative inotropic effect than verapamil and diltiazem, but still may worsen HF. Amlodipine may have the least negative inotropic effect.

[d] All have poor bioavailability owing to high first-pass metabolism and all are eliminated primarily by hepatic metabolism; intradivisional and interindividual variability in bioavailability and metabolism is extensive. Diltiazem, nifedipine, nicardipine, and verapamil have a short half-life (<5 hours) requiring frequent dosing or use of sustained-release products. Amlodipine, isradipine (8 hours), and felodipine (10–20 hours) have longer half-lives.

[e] See Table 12-5

[f] Hypotension and reflex tachycardia most with immediate-release nifedipine, occasional with immediate-release diltiazem and verapamil, minimal with sustained-release products or intrinsically long-acting agents.

CASE 12-2, QUESTION 3: Six months later, B.N. returns to see his physician. His current therapy consists of SL NTG 0.4 mg tablets, losartan 100 mg once daily, fluticasone inhaler two puffs twice daily, albuterol inhaler two puffs as needed, aspirin 81 mg daily, atorvastatin 20 mg daily, and diltiazem 180 mg once daily. Current vitals include a resting heart rate of 55 beats/minute, BP of 115/65 mm Hg, and respiratory rate of 10 breaths/minute. B.N. states he still is having roughly three to four anginal attacks per week when he exerts himself doing yard work. Would ranolazine be a therapeutic option for his chronic stable angina at this time?

Although higher doses of diltiazem might be attempted in B.N., his current heart rate and BP would likely prevent further titrating of therapy. β-Blocker therapy is not a good option due to the potential reduction in heart rate and asthma. Thus, ranolazine represents a good option for B.N. at this time due to the absence of heart rate and BP-lowering effects with ranolazine. Several large, randomized studies with ranolazine have been conducted, all demonstrating its effectiveness at reducing ischemia and angina when added to existing therapy. The Monotherapy Assessment of Ranolazine in Stable Angina (MARISA) trial randomly assigned patients in a crossover fashion who had met screening criteria to either escalating doses of ranolazine (500 mg BID, 1,000 mg BID, 1,500 mg BID) or placebo. All other antianginal agents, except for SL NTG, were discontinued. Ranolazine significantly increased exercise duration, time to onset of angina, and 1-mm ST-segment depression during exercise treadmill testing.[80] Similar results were seen in the Combination Assessment of Ranolazine in Stable Angina (CARISA) trial in which ranolazine (500 mg BID, 750 mg BID, 1,000 mg BID) was added to antianginal monotherapy that consisted of atenolol, diltiazem, or amlodopine.[81] The Efficacy of Ranolazine in Chronic Angina (ERICA) trial assessed the effects of ranolazine added to amlodipine 10 mg/day. Up to one-half of the patients enrolled in ERICA were also on a long-acting nitrate. Patients were randomly assigned to either placebo or ranolazine 500 mg/day for 1 week and then to 1,000 mg/day for an additional 6 weeks. Patients receiving 1,000 mg/day of ranolazine had a significant reduction in both the number of weekly anginal attacks, as well as the number of SL NTG tablets used.[82] A reduction in the frequency of angina was also seen in patients with CAD and diabetes mellitus when ranolazine was added in the Type 2 Diabetes Evaluation of Ranolazine in Subjects with Chronic Stable Angina (TERISA) study.[83] Ranolazine was well tolerated in all four of these trials with the most common side effects being dizziness, constipation, nausea, and headache. The incidence of adverse effects increased with increasing doses. No other significant adverse effects were noted, although it is important to note that the duration of these trials was limited.[41]

Information regarding the safety of ranolazine in patients with longer drug exposure came from the Ranolazine Open Label Experience (ROLE) program,[84] which followed patients from the MARISA and CARISA trials who continued in an open-label extension program. A total of 746 patients initially entered the 6-year run-on safety program. At the time of publication, the mean duration of therapy was 2.82 years, with 23.3% of patients

---

discontinuing therapy. One-half of the withdrawals were because of adverse events, but the incidence of common adverse effects did not seem to change from that seen in the randomized portions of the clinical trials. Mortality rates at both 1 year (2.8%) and 2 years (5.6%) indicate no adverse risk of ranolazine on overall mortality.

The Metabolic Efficiency with Ranolazine for Less Ischemia in Non–ST-Elevation Acute Coronary Syndrome (MERLIN)-TIMI 36 trial[85] randomly assigned patients to ranolazine or placebo in the setting of ACS. Ranolazine was administered as an intravenous (IV) infusion for 12 to 96 hours, then converted to 1,000 mg twice daily. Patients were assessed for clinical end points during the acute hospitalization, then every 4 months thereafter. The incidence of recurrent ischemia was significantly reduced with ranolazine providing additional support for the efficacy of ranolazine in treating chronic stable angina. Although ranolazine appeared to offer no benefit in the setting of ACS, significant long-term safety data were seen in the trial. Importantly, the risk of mortality, sudden cardiac death, or symptomatic arrhythmias was not increased with ranolazine versus placebo. In fact, the incidence of arrhythmias in the first 7 days, as documented by Holter monitor, was significantly lower with ranolazine than with placebo.[86] This was an important finding given ranolazine produces a dose-dependent increase in the QT interval.[15,41] As QT prolongation activity has been associated with proarrhythmia in other medications, results from the MERLIN trial are reassuring that ranolazine appears to be safe to use for chronic treatment of patients with stable angina.

B.N. is at goal heart rate, and his BP is well controlled on his current regimen, but he continues to have anginal symptoms. Given the demonstrated efficacy in relieving anginal symptoms, as well as the safety profile in a patient like B.N., ranolazine would be an excellent option for him for additional angina control.

CASE 12-2, QUESTION 4: How should ranolazine be dosed in B.N.?

Ranolazine is marketed as an extended-release tablet formulation that should be dosed twice daily. Maximal plasma concentrations are observed 4 to 6 hours after administration of the extended-release formulation with a terminal half-life of 7 hours. With twice-daily dosing of the extended-release preparation, a more favorable peak-to-trough fluctuation of 1.6 is observed.[41] Steady-state is typically reached within 3 days and oral bioavailability is 30% to 55%. Ranolazine is primarily metabolized by the liver through CYP3A4 (70%–85%) and CYP2D6 (10%–15%). Ranolazine also is a substrate for P-glycoprotein.[15,41] Patients should initially be started at an oral dose of 500 mg twice daily, which can be titrated up to a maximal dose of 1,000 mg twice daily.[120]

Although ranolazine is an option in the treatment of chronic stable angina, careful patient selection is required for the drug to be used safely and effectively.[120] Table 12-7 summarizes significant issues, which should be evaluated when the drug is being considered for a patient. For B.N., the main issue is the drug–drug interaction with diltiazem, and the maximum dose of ranolazine that should be used in patients receiving diltiazem is 500 mg twice daily. B.N. should be monitored closely for possible increased adverse effects with ranolazine.

CASE 12-3

QUESTION 1: E.R. is a 58-year-old woman with a history of chronic stable angina for the last several years that has been managed primarily with medical therapy. Her current medications include oral isosorbide mononitrate 120 mg daily, oral metoprolol succinate 200 mg daily, ranolazine 1,000 mg twice daily, fluticasone two puffs BID, albuterol two puffs as needed, NTG spray 0.4 mg as needed for chest pain, and enteric-coated aspirin 81 mg/day. Today she returns to your pharmacy to obtain refills of her medications with her 64-year-old brother who wants to know if he should be taking an aspirin a day to prevent heart disease. His only medical history consists of hypertension for which he is taking oral hydrochlorothiazide 25 mg every day. Is primary prevention of CAD with aspirin appropriate for E.R.'s brother?

Table 12-7

Considerations for the Use of Ranolazine in Patients with Chronic Stable Angina[15,41,120]

Clinical Issue	Recommended Management Strategy
Renal insufficiency	Ranolazine plasma levels may increase up to 50%. Caution with dose titration to maximal recommended dose
Hepatic insufficiency	Ranolazine is contraindicated in patients with clinically significant hepatic impairment
Drug Interactions: Effects on Ranolazine	
Strong CYP3A4 inhibitors	Plasma concentrations of ranolazine are significantly elevated when combined with potent inhibitors of CYP3A4. Ranolazine is contraindicated in patients receiving strong CYP3A4 inhibitors (ketoconazole, clarithromycin, nelfinavir, etc.)
Moderate CYP3A4 inhibitors	Limit the dose of ranolazine to 500 mg twice daily in patients receiving moderate inhibitors of CYP3A4 (diltiazem, verapamil, erythromycin, fluconazole, etc.)
CYP3A4 inducers	Coadministration of ranolazine with CYP3A4 inducers is contraindicated and should be avoided

P-glycoprotein inhibitors	Caution should be exercised when coadministering ranolazine with P-glycoprotein inhibitors, and the dose of ranolazine may need to be lowered based on clinical response
Drug Interactions: Effects on Other Medications	
Simvastatin	Plasma levels of simvastatin are increased twofold with coadministration with ranolazine through CYP3A4 inhibition by ranolazine; closely monitor for adverse effects (e.g., myositis) from simvastatin
Digoxin	Ranolazine coadministration increases plasma concentrations of digoxin by 1.5 times. Adjust dose of digoxin accordingly to maintain desired therapeutic level and response
CYP2D6 substrates	Ranolazine can inhibit the activity of CYP2D6, and plasma concentrations of 2D6 substrates (β-blockers, tricyclic antidepressants, antipsychotics) may be increased and lower doses of these agents may be required
QT prolongation	Caution is recommended if the patient is on other QT prolonging drugs, or has QT prolongation as baseline

---

The question of whether aspirin is valuable in the primary prevention of cardiovascular events has been debated for more than 20 years. The absolute risk–benefit ratio for aspirin in primary prevention will depend on the overall absolute risk of vascular ischemic events. Several meta-analyses suggest that any benefit for aspirin in reducing ischemic events is offset by an increase in bleeding, resulting in no net clinical benefit.[87–90]

In 2009, the US Preventative Services Task Force developed updated guidelines for aspirin use in primary prevention incorporating at the time of the most recent published evidence.[91] Recommendations are differentiated initially by age and sex, recognizing that the ischemic benefit varies between men (reduction in nonfatal MI) and women (reduction in ischemic stroke). Aspirin for primary prevention may be considered for men aged 45 to 79 years, and in women aged 55 to 78 years. Because E.R.'s brother is 64 years of age, it is appropriate for him to consider the use of aspirin for primary prevention. The first step is to calculate what his risk is for developing CVD.[25] This can be done by using a validated risk assessment scoring system, such as the Framingham risk score (see Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease). Based on his age, if his 10-year risk of CVD is greater than 9%, the CVD benefit with aspirin will outweigh any potential bleeding harm according to the US Preventative Service Guidelines.[91] Recognizing the existing controversy surrounding the use of aspirin for primary prevention, a thorough review of the potential risk and benefits should take place with E.R.'s brother so that he may make the most informed decision possible.

CASE 12-3, QUESTION 2: E.R also buys a bottle of over-the-counter ibuprofen. On further questioning, you learn that E.R. suffers from occasional back and knee pain and uses ibuprofen three to five times a week for pain relief. How should E.R. be educated regarding the use of ibuprofen and aspirin concomitantly?

In 2006, the FDA released a warning statement on the concomitant use of both aspirin and ibuprofen. The impetus for the statement was the growing recognition that nonsteroidal antiinflammatory drugs (NSAIDs), in particular ibuprofen, may attenuate the antiplatelet effects of low-dose aspirin. This FDA warning was then followed by an updated scientific statement, from the AHA.[92] The mechanism of this interaction is that both aspirin and nonselective NSAIDs bind to the same acetylation sites of the cyclooxygenase enzyme. Although aspirin does this in a nonreversible fashion, binding by an NSAID occurs in a reversible fashion. If an NSAID, such as ibuprofen, is present, aspirin will be unable to bind to its site of action, and will be rapidly cleared from the plasma. The result is the patient will not receive the antiplatelet benefit of aspirin.

E.R. should be counseled on the consequences of the interaction between her aspirin and ibuprofen. Additionally, if she can avoid or at least minimize (both dose and duration) the use of ibuprofen, the effect on her cardiovascular health would be optimized. If occasional use of ibuprofen cannot be avoided, it should be administered to minimize the potential for interacting with her aspirin. This would include taking ibuprofen at least 2 hours after her daily dose of aspirin, as well as taking her daily aspirin dose at least 8 hours after the last dose of ibuprofen. Although similar concerns exist for other nonselective NSAIDs (naproxen, diclofenac), no formal recommendations exist on how to manage concomitant use of these agents with aspirin.[92] Beyond the potential drug–drug interaction with aspirin therapy, there has emerged a large body of observational evidence that the use of NSAIDs in patients with underlying CVD may increase the risk of major adverse cardiovascular events. Although the underlying mechanisms remain to be determined, clinicians should minimize the use of NSAIDs if possible in patients with underlying CVD.[93]

REVASCULARIZATION

Percutaneous Coronary Intervention

CASE 12-3, QUESTION 3: Nine months later, E.R. returns to her cardiologist stating that her chronic angina has been worsening. She is experiencing chest pain more frequently and much sooner when she does any type of physical activity. Her current medications are the same as discussed previously and it is felt that her medical management has been optimized as much as possible. After discussions with her cardiologist, she elects to undergo revascularization with PCI for symptom relief. What is the current standard for prevention of acute complications during PCI?

PCI, also known as angioplasty, involves the percutaneous insertion of a balloon catheter into the femoral or brachial artery. The catheter is advanced up the aorta and into the coronary arteries at the coronary sinus. PCI initially involved the inflation of a catheter-borne balloon that mechanically dilated a coronary artery obstruction through arterial intimal disruption, plaque fissuring, and stretching of the arterial wall. Balloon inflations were repeated until the plaque was compressed and coronary blood flow resumed. Since then, alternative devices have been developed, including rotational blades designed to remove atheromatous material, lasers to ablate plaques, and intracoronary stents that are designed to maintain the patency of the vessel after it is reopened.[94] Stents can be of the bare-metal (BMS) variety, or contain a drug impregnated on the surface of the stent to prevent restenosis (DES). It is estimated that more than 1,265,000 PCI procedures are performed in the United States each year. An overwhelming majority of these procedures involve placement of a BMS or DES (Fig. 12-5). PCI is indicated in patients with single-vessel or multi-vessel disease and who are either symptomatic or asymptomatic.[20,94,95]

Because of mechanical disruption of the atherosclerotic plaques and exposure of plaque contents to the bloodstream during PCI, potent antiplatelet and antithrombotic strategies are needed to prevent acute thrombotic events such as MI and death. Current strategies in patients undergoing elective PCI involve the administration of aspirin, a $P2Y_{12}$ antagonist (clopidogrel, prasugrel, or ticagrelor), an antithrombin agent, and occasionally a glycoprotein (GP) IIb/IIIa receptor antagonist in selected patients. Although ticagrelor and prasugrel represent alternatives to clopidogrel in patients undergoing PCI, current ACC/AHA guidelines recommend their use only in patients undergoing PCI in the setting of ACS. In patients not taking aspirin on a daily basis, 300 to 325 mg of aspirin should be given at least 2 hours before the procedure. Patients currently on daily aspirin therapy should receive 75 to 325 mg of aspirin before PCI is performed. A 600-mg loading dose of clopidogrel on or before the time of the procedure is currently recommended, producing an antiplatelet action within 2 hours.[16,17,20,95] Adequate antithrombin therapy such as unfractionated heparin, the low-molecular-weight heparin enoxaparin, or the direct thrombin inhibitor bivalirudin should be used in patients having elective PCI.[20,95] (See Chapter 13, Acute Coronary Syndrome, for more information.)

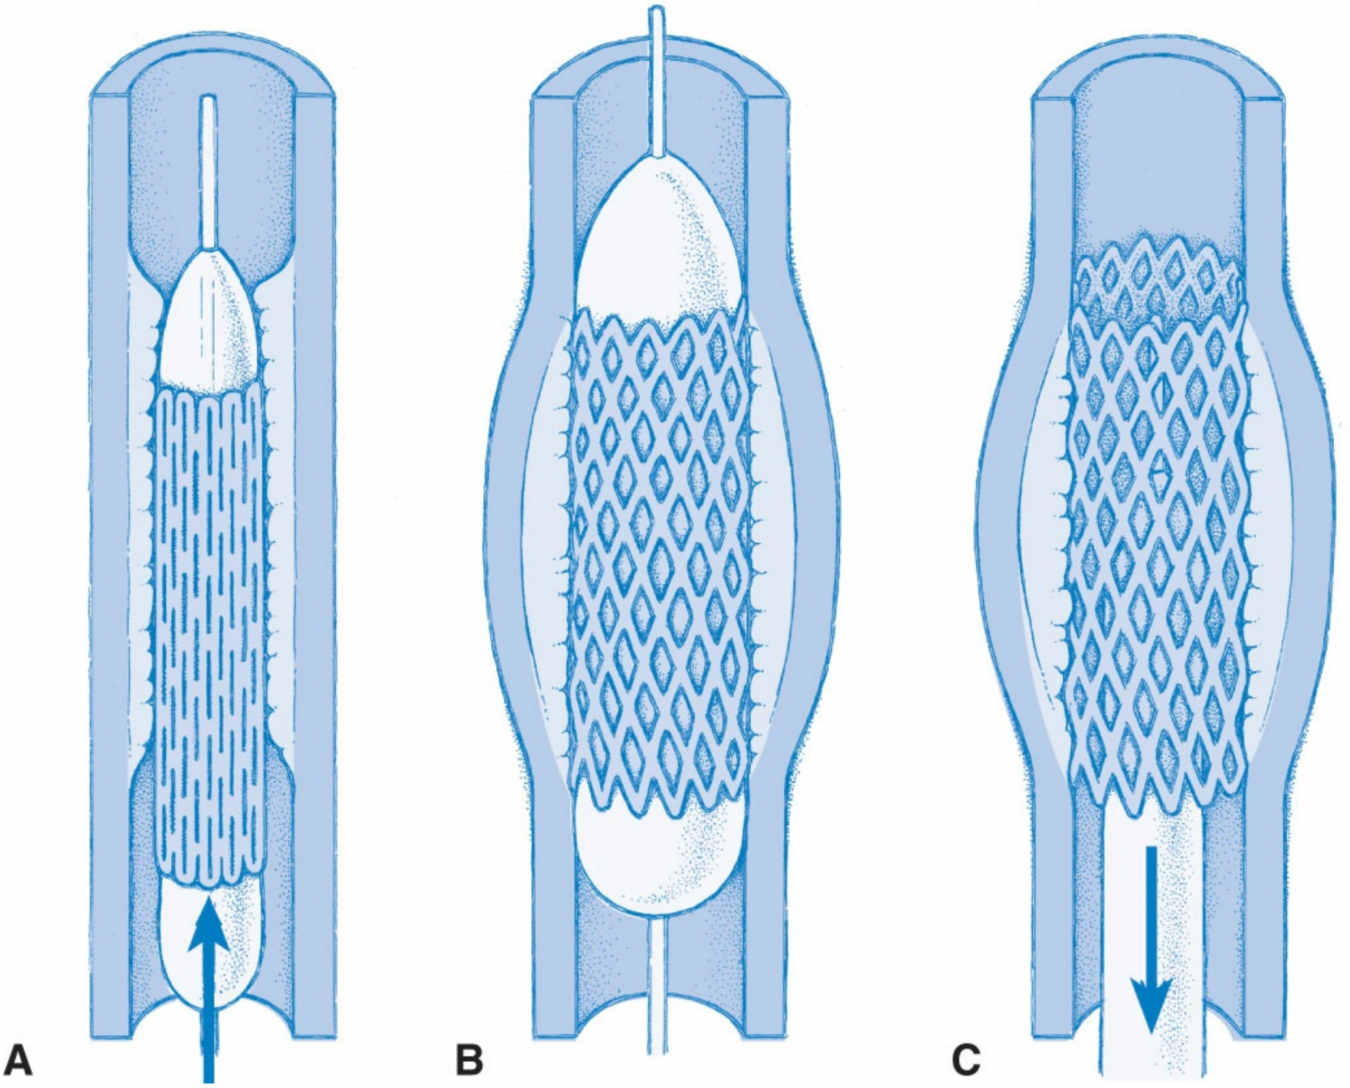

Figure 12-5 Vascular stent. **A:** A balloon catheter positions the stent at the site of arterial stenosis. **B:** Inflation of the balloon dilates the artery and expands the stent. **C:** The balloon is collapsed and withdrawn, leaving the expanded stent in position. (Illustration by Neil O. Hardy, Westpoint, CT.)

CASE 12-3, QUESTION 4: E.R. undergoes PCI plus placement of a DES to address a 75% lesion in her proximal left circumflex artery. What advantages and disadvantages are there in the decision to place a DES versus a BMS?

The overall success of any procedure is directly related to the experience of the operator, patient factors (such as LV function or number of vessels treated), and the equipment used. In patients receiving balloon angioplasty alone (without stent placement), repeat revascularization procedures (either repeat angioplasty or surgery) may be required in as many as 32% to 40% of cases because of lesion recurrence at the angioplasty site. The process is known as restenosis.[94] Many pharmacologic strategies have been studied in an attempt to reduce the risk of restenosis. The outcome with most methods has been disappointing. The only strategy that has been associated with a decrease in restenosis is the use of intraluminal stents.[94] Stents are essentially metal scaffolding devices placed into the vessel after balloon inflation has taken place. They provide a physical barrier to the recurrence of a significant stenosis at the site. One of the early drawbacks of the use of stents was the need for complicated antithrombotic regimens, including aspirin, heparin, dipyridamole, and warfarin, to prevent in-stent thrombosis. DAPT—a combination of a $P2Y_{12}$ antagonist and aspirin—is effective at reducing in-stent thrombosis and is now recommended for use after stent placement.[20,95] The duration of DAPT will depend on the type of stent used, as well as other clinical characteristics of the patient.

Recently, stents that elude antiproliferative agents such as sirolimus, paclitaxel, zotarlimus, or everolimus have been shown in clinical trials to reduce the incidence of restenosis compared with BMS.[96] Restenosis rates in clinical trials with these DES were in the single-digit range, as compared to 15% to 20% with traditional BMS. Soon after their introduction to the US market, DES use grew to the point that greater than 90% of stent use was DES. This trend abruptly halted in the fall of 2006 when several reports indicated a higher than expected incidence of stent thrombosis a year or more after DES placement. Although late stent thrombosis had previously been reported with BMS usage, the incidence was rare.[20] Shortly after these initial reports, an explosion of scientific literature emerged on the topic. Delayed endothelialization is seen with DES compared with BMS. After placement of an intracoronary stent, a healing process typically occurs resulting in growth of a protective layer of endothelial cells over the stent surface, removing the stent surface from blood exposure and drastically reducing the stimulus for thrombosis. In the case of DES coated with paclitaxel, sirolimus, or everolimus, cellular growth may be inhibited, significantly impairing endothelialization of the stent surface. In a small number of patients, endothelialization does not seem to occur at all. In this scenario, the stent structure remains continually exposed to flowing blood and is a potent stimulus for thrombosis.[97] Because of the concerns of late stent thrombosis, the usage of DES has decreased. Some use of DES is likely to continue, however, owing to the tangible benefits in reduction of revascularization procedures in some patients. Therefore, practitioners will need to continue to stay abreast of evolving information regarding appropriate strategies to prevent late stent thrombosis.

One critical issue that has been identified as a cause of late stent thrombosis with DES is the premature discontinuation of DAPT. As such, consideration of whether the patient is likely to comply with aspirin and $P2Y_{12}$ antagonist therapy, or afford such therapy based on insurance status, has become a significant factor in the decision process between using a BMS or DES. Previous recommendations called for varying durations of combined therapy, depending on the type of stent used. Because of the recognition of a delayed healing response to DES, current guidelines recommend at least 1 year of DAPT in patients receiving a DES if patients are not at an elevated risk of bleeding. For BMS placement, DAPT should continue for a minimum of 1 month, and up to 1 year ideally, but this extended duration is not as critical as it is in the setting of DES placement. After PCI, it is reasonable to use aspirin 81 mg daily rather than higher doses.[20] The dose of clopidogrel should be 75 mg/day.[20,95]

CASE 12-3, QUESTION 5: Would revascularization therapy with coronary artery bypass grafting have been a better option for E.R. than PCI and stent placement?

Coronary artery bypass grafting is a complicated surgical procedure during which an atherosclerotic vessel is bypassed using either a patient's saphenous vein or internal mammary artery (IMA; Fig. 12-6). The graft (i.e., the saphenous vein or IMA) then allows blood to flow past the obstruction in the native vessel. The goals of antianginal therapy, whether medical (pharmacologic) or revascularization, remain unchanged: (a) to prolong life, (b) to prevent MI, and (c) to improve the quality of life.

The outcomes of medical therapy, PCI, and revascularization with CABG have been compared, and current guidelines are available.[1,21] When compared with medical treatment in patients who would not be considered high risk, PCI in general offers no improvement in the long-term incidence of MI or cardiovascular death, but significantly reduces symptoms.[1] Because of her escalating symptoms on triple drug therapy, the choice of PCI for E.R. is justified.

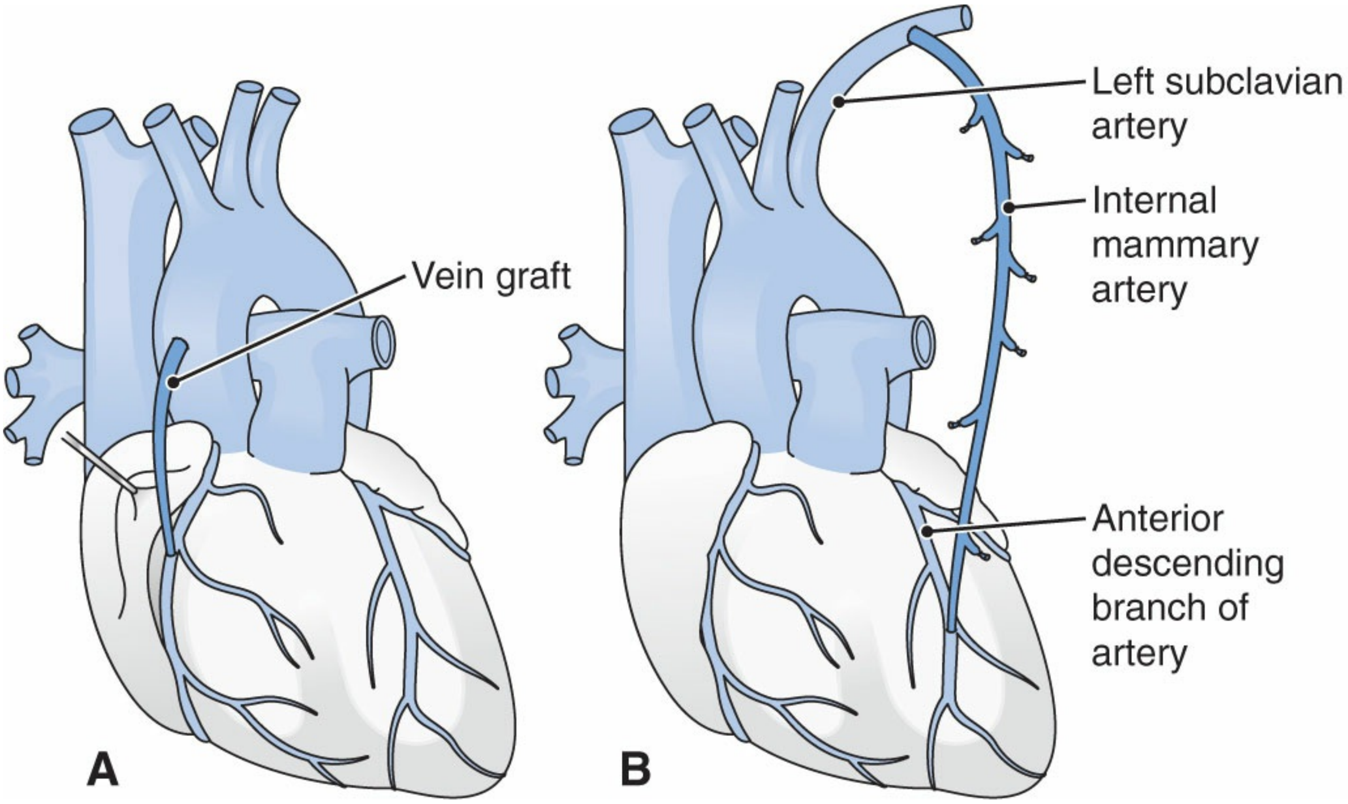

Figure 12-6 Coronary artery bypass graft (CABG). **A:** A segment of the saphenous vein carries blood from the aorta to a part of the right coronary artery that is distal to an occlusion. **B:** The mammary artery is used to bypass an obstruction in the left anterior descending (LAD) coronary artery. (Reprinted with permission from Cohen BJ. Medical Terminology. 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003.)

Certain high-risk patient subgroups clearly have an improved outcome with CABG. These include (a) patients with significant left main coronary disease; (b) patients who have three-vessel disease, especially with LV dysfunction; (c) patients with two-vessel disease with a significant proximal LAD lesion; (d) patients who have survived sudden cardiac death; and (e) patients who are refractory to medical treatment. In patients who do not meet these criteria, either medical treatment or PCI is a viable option.[1,20] Because E.R. does not fall into one of these categories, PCI is preferable owing to the less invasive nature of the procedure and the equivalent outcomes that are seen. These results were recently confirmed in the Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation (COURAGE) trial.[43] Patients with CAD were randomly assigned to aggressive medical treatment with optimization of medical therapy and risk factors, or aggressive medical treatment plus PCI. During a 4.6-year period, no significant difference was noted between the groups in cardiovascular outcomes (death, MI, stroke, hospitalization for ACS). The only difference noted was better control of anginal symptoms early on with PCI, but that difference was no longer significant at the end of the study. These results highlight the crucial role of optimizing medical therapy (including diet, lifestyle changes, risk factor modification) for patients with CAD, regardless of whether revascularization is performed.[1]

CASE 12-3, QUESTION 6: E.R. undergoes PCI plus stent placement and returns to your pharmacy to have a new prescription filled. The prescription calls for clopidogrel at a dose of 150 mg once a day for 1 week, then 75 mg a day thereafter with 11 monthly refills. You have not seen clopidogrel dosed in such manner and are wondering what the rationale for the higher dose is, and whether there is evidence to support its use.

Clopidogrel, a thienopyridine, inhibits platelet function as a noncompetitive antagonist of the $P2Y_{12}$ platelet adenosine diphosphate receptor. Clopidogrel is dosed at 75 mg daily, and this dose has been demonstrated to be effective and safe as monotherapy, or as a component of DAPT with aspirin, in a wide variety of settings for patients with CAD.[98] Despite proven efficacy, patients continue to experience clinical events while receiving clopidogrel.[99] It is now understood that clopidogrel does not produce a consistent antiplatelet response in many patients.[100]

Although the term clopidogrel resistance was first used to describe patients who do not have the expected antiplatelet response to standard doses of clopidogrel, a better term to describe this phenomenon is clopidogrel nonresponsiveness. Alternatively, the phrase high on-treatment platelet reactivity is also used commonly in the literature, especially when characterizing the clinical consequences of decreased antiplatelet response.[100] The presence of high on-treatment platelet reactivity in patients who have undergone PCI has been linked to a higher rate of stent thrombosis, MI, repeat revascularization, and death. This link has been observed in both stable CAD patients undergoing elective PCI, and patients with

ACS. Although nonresponsiveness identifies an elevated risk for ischemic events, not all patients with identified clopidogrel nonresponsiveness necessarily go on to have recurrent events.[99]

There is a lack of consistency of how clopidogrel nonresponsiveness is defined. It may be defined as the presence of a recurrent ischemic event while on therapy. But, thrombosis is a complex interplay of many different factors and recurrent clinical events do not necessarily imply a lack of antiplatelet effect. The identification of a lack of the expected biologic effect on platelet function is a more appropriate definition to work with. However, there are multiple tests available to assess the antiplatelet activity of clopidogrel (and other antiplatelet agents), and it is unclear which assay correlates best with clinical outcome and would be preferred to assess clopidogrel nonresponsiveness. Because of the variability in available platelet function tests, as well as definitions of nonresponsiveness, estimates for the incidence of clopidogrel nonresponsiveness range anywhere from 5% to 44%.[100] Table 12-8 lists some of the available laboratory testing modalities for antiplatelet agents, their pros and cons, as well as previously identified levels of high on-treatment platelet reactivity.[101]

Potential reasons for clopidogrel nonresponsiveness are multifactorial. One source of nonresponsiveness is in the decreased biotransformation of clopidogrel from its prodrug form to its active metabolite. Biotransformation is a multistep process through the cytochrome P-450 system, but the most important enzyme is CYP2C19, which exhibits variable metabolic capacity. Patients with the *1/*1 CYP2C19 alleles are considered extensive metabolizers and are capable of generating sufficient levels of clopidogrel's active metabolite. Patients with one or two copies of either the *2 or *3 alleles (considered loss of function alleles) are considered either intermediate or poor metabolizers, generate lower amounts of active metabolite, and generally produce a reduced antiplatelet effect as measured with available platelet function testing.[102] Conversely, patients with one or two copies of the *17 allele (considered a gain of function allele) are considered ultrarapid metabolizers and demonstrate a heightened antiplatelet response with clopidogrel. With the unraveling of pharmacogenomic factors related to clopidogrel response, a great deal of attention has been given to the idea of identifying patients with copies of either the *2 or *3 allele and adjusting antiplatelet therapy accordingly. The FDA added language to the clopidogrel package insert specifying that poor metabolizers have a higher cardiovascular event rate, and that tests are available to identify who those patients are who carry these genes.[103] Although the presence of either loss of function allele has been associated with an increased risk of clinical outcomes in some trials, this finding has not been uniformly observed. Additionally, there are no prospective trials evaluating a strategy of genetic testing with subsequent therapy changes. As such, genetic testing related to clopidogrel therapy is considered to be in the investigational stage.

Table 12-8

Commonly Used Platelet Function Tests for Assessment of Antiplatelet Effects[121,122]

Test	Pros	Cons	Monitoring Key Points
Turbidimetric aggregometry, commonly referred to as light transmission aggregometry or LTA	Historical gold standard	Large blood volume Expensive Poor reproducibility Time-consuming Technical complexity	Whole blood assay Can be used for multiple antiplatelet agents with variable reagents
VASP phosphorylation	Whole blood assay Small blood volume needed	Technical complexity Expensive Requires a flow cytometer	Specific for thienopyridines Cutoff for antiplatelet nonresponsiveness ■ PRI > 50%
VerifyNow	True point-of-care assay Large number patients studied Whole blood assay Simple and rapid	Cartridge cost Limited ranges for hematocrit and platelet count	Can assess multiple antiplatelet agents Cutoff for antiplatelet nonresponsiveness ■ PRU >235–240
Thromboelastography	Whole blood assay Point of care	Limited clinical studies Substantial pipetting of reagents	Can assess multiple antiplatelet agents

PRI, platelet reactivity index; PRU, platelet reaction units; VASP, vasodilator-stimulated phosphoprotein.

An alternative approach to address the issue of clopidogrel nonresponsiveness is to assess platelet function in patients receiving clopidogrel. To date, trials conducted have indicated that increasing loading or maintenance doses of clopidogrel do have the potential to convert patients deemed nonresponders to responders.[104] However, not all patients can be converted and no trial has demonstrated that such an approach leads to improved clinical outcomes.[105] Additionally, data indicate no improvements in clinical outcomes from platelet function monitoring.[106]

Empirically using higher doses of clopidogrel in all patients undergoing PCI is an additional approach that has been considered in addressing clopidogrel nonresponsiveness. Although no trials have been conducted in the elective PCI setting, the CURRENT-OASIS 7 trial randomly assigned more than 25,000 ACS patients to either standard dosing of clopidogrel (300 mg load, then 75 mg daily) or a higher dosing regimen (600 mg load, then 150 mg daily for 7 days, then 75 mg daily).[107] Patients were also randomly assigned to either high-dose (300–325 mg daily) or low-dose (75–100 mg daily) aspirin. Approximately 17,000 of the 25,000 patients underwent PCI. Results showed that in PCI patients, the higher dosing regimen of clopidogrel reduced the risk of MI at the cost of a higher incidence of major bleeding.

Although the results of the CURRENT-OASIS 7 trial might be viewed in a positive light in relation to the prescription E.R. is presenting with today in your pharmacy, an important caveat is that the CURRENT-OASIS 7 trial was conducted in ACS patients, and it is unclear if the same benefits (and risks) can be expected in patients undergoing elective PCI for symptom management of chronic stable angina.

CASE 12-3, QUESTION 7: While you are filling her new clopidogrel prescription, E.R. mentions that she has been having some problems with heartburn lately and asks where she can find some over-the-counter omeprazole. Is omeprazole appropriate to use in a patient with clopidogrel therapy?

Another source of variable clopidogrel response is through potential drug–drug interactions involving the CYP2C19 enzyme. One class of agents that has generated substantial controversy in this area are the proton-pump inhibitors (PPIs), given the likelihood of coadministration to prevent GI bleeding as a result of antiplatelet therapy. Several studies indicate there is a pharmacokinetic interaction between PPIs, in particular omeprazole, with clopidogrel resulting in reduced levels of the active metabolite. Evidence that this interaction is clinically significant is variable. Several retrospective analyses suggest an increased risk for CVD events in patients taking PPIs with clopidogrel therapy.[108–112] However, the available evidence from randomized controlled trials does not support an increased clinical risk with this combination.[112–114] However, one study has identified that PPI use alone is associated with an elevated risk of CVD events.[115] Clinicians are faced with addressing this issue from a medical–legal aspect as the FDA has incorporated language into the clopidogrel package insert warning against the concomitant administration of omeprazole and esomeprazole with clopidogrel.[116] The recommendation applies to omeprazole and esomeprazole but not other PPIs. There is some evidence to suggest that alternative PPIs such as pantoprazole have a lower propensity to inhibit CYP2C19 and interact with clopidogrel. Until further information becomes available, clinicians should first validate the need for PPI therapy in clopidogrel patients. If acid suppressive therapy is needed, the use of a H_2 antagonist (excluding cimetidine which can inhibit CYP enzymes) or a PPI less likely to interact with clopidogrel would seem to be appropriate options to consider.[117]

VARIANT ANGINA (CORONARY ARTERY SPASM)

Clinical Presentation

CASE 12-4

QUESTION 1: A.P., a 35-year-old woman, is hospitalized for evaluation of severe chest pain, which occurs almost daily at about 5 AM. A.P. ranks the severity of pain as 7 to 8 on a scale of 1 to 10. It is associated with diaphoresis and is not relieved by change in position. A.P. has no cardiovascular risk factors, and her hobbies include triathlon competition and rock climbing, neither of which has caused chest pain. She follows a strict vegetarian diet and takes no medications. Admission ECG reveals sinus bradycardia at 56 beats/minute. Serum electrolytes, chemistry panel, and cardiac enzymes are all within normal limits.

On day 1 of hospitalization, A.P. is awakened at 6 AM abruptly by severe chest pain. Her vital signs at this time include the following: heart rate, 55 beats/minute; supine BP, 110/64 mm Hg; and respiratory rate, 12 breaths/minute. An ECG shows sinus bradycardia with marked ST-segment elevation. The pain is relieved within 60 seconds by one NTG 0.4-mg sublingual tablet. During the day, she completes an exercise tolerance test without complication or evidence of CAD.

On the second day, A.P. undergoes cardiac catheterization, and no coronary atherosclerosis is visualized. A.P. is diagnosed as having Prinzmetal variant angina. Discharge medications include oral amlodipine 10 mg every day at 11 PM and NTG lingual spray 0.4 mg as needed for chest pain.

Is A.P.'s presentation typical for Prinzmetal variant angina?

A.P. presents with a classic picture of variant (Prinzmetal) angina, with transient total occlusion of a large epicardial coronary artery as a result of severe segmental spasm. Clinical manifestations include chest pain occurring at rest, often in the morning hours. As with A.P., patients with Prinzmetal variant angina generally are younger than patients with chronic stable angina and do not carry a high-risk profile. Other vasospastic disorders, such as migraine attacks or Raynaud's phenomenon, may be present; smoking and alcohol ingestion can be important contributing factors.[118]

The hallmark of variant angina is ST-segment elevation on the ECG, which denotes rapid and complete occlusion of the coronary artery. Many patients also have asymptomatic episodes of ST-segment elevation. Transient arrhythmias and conduction disturbances may be observed during pain, depending on the severity of the myocardial ischemia.[118]

As documented by angiography, A.P. has vasospasm of the large RCA. This transient, reversible narrowing is probably caused by increased coronary vascular resistance. It can occur in the absence of atherosclerosis, as illustrated by A.P., and also in the presence of CAD. One possible explanation for vasospasm occurring more commonly at night or during the early morning hours is increased vasomotor tone secondary to diurnal variations in catecholamines.

Therapy

CASE 12-4, QUESTION 2: Oral amlodipine 10 mg every day was ordered for A.P. Would long-acting nitrates or β-adrenergic blockers be reasonable alternatives to amlodipine for A.P.? Is one CCB preferable to another for treatment of Prinzmetal variant angina?

Because of their antispasmodic effects and low incidence of side effects, CCBs are generally selected over nitrates or β-blockers for nocturnal vasospastic angina. All CCBs appear equally effective in preventing Prinzmetal variant angina.[118] Intrinsically long-acting or sustained-release forms are preferred, however, and some patients may respond better to one agent than to another.

In patients who continue to experience pain using maximal CCB doses, combination therapy with a nitrate should be tried. Nitrates cause vasodilation by a different mechanism than CCBs and are effective in treating Prinzmetal variant angina.[118] To avoid tolerance, the nitrate-free interval for A.P. should be scheduled during the day so that the early morning hours when vasospasm occurs are covered by NTG. For example, A.P. could apply a transdermal NTG patch at bedtime and remove it on awakening. Statin therapy is indicated for A.P.[118]

Blockade of the β_2-receptors that mediate vasodilation may allow unopposed α_1-mediated vasoconstriction with worsening symptoms. Even a cardioselective β-blocker could worsen Prinzmetal variant angina.[118] Therefore, a CCB or nitrate is preferred.

CASE 12-4, QUESTION 3: Will A.P. require treatment for the remainder of her life?

During the first year of therapy, up to 50% of patients experience spontaneous remission by an unknown mechanism.[118] This occurs most often in patients who have had a short duration of symptoms or who have normal or mildly diseased coronary arteries (i.e., isolated vasospasm without atherosclerosis). If A.P. is pain free and not experiencing significant arrhythmias or silent ischemic episodes of Prinzmetal angina after 1 year, amlodipine could be tapered and discontinued. It is also possible, however, that she will require treatment indefinitely. Modification of smoking and ethanol ingestion may promote remission of Prinzmetal angina.[118]

CARDIAC SYNDROME X

CASE 12-5

QUESTION 1: K.G., a 50-year-old female executive, has undergone an extensive cardiovascular workup for exertional angina associated with a 3-mm ST-segment depression. A recent cardiac catheterization did not reveal any atherosclerosis. The cardiologists believe K.G. has cardiac syndrome X. What drug therapy might be indicated for K.G.?

Cardiac syndrome X is a syndrome of angina or angina-like chest pain in the setting of a normal coronary arteriogram, and ST-segment depression during exercise. Several theories exist regarding the mechanism of pain production, including microvascular dysfunction producing ischemia or chest discomfort without ischemia in patients who may have an abnormal perception of pain. Half of patients with cardiac syndrome X present with chest pain induced by exercise followed by 15 to 20 minutes of chest discomfort.[119]

By symptoms alone, K.G.'s presentation does not significantly differ from that of a patient with exercise-induced angina secondary to atherosclerosis. Of concern is the finding of a 3-mm ST-segment depression on K.G.'s ECG, which raises concern of severe CAD. The negative findings from her cardiac catheterization, however, rule against both CAD and coronary artery spasm as a cause of her symptoms, and help to confirm the diagnosis of cardiac syndrome X.[119]

Treatment with a nitrate, CCB, or β-blocker all appear to offer some relief, but overall the response to therapy in these patients is poor. The choice of agent will likely depend on specific patient characteristics. Sublingual NTG is often ineffective at treating acute attacks, although it should still be prescribed. Often a combination of anti-ischemic therapy, analgesic therapy, and lifestyle modifications is necessary.[119]

Acute Coronary Syndrome

Brianne L. Dunn and Robert L. Page, II

CORE PRINCIPLES		CHAPTER CASES
ACUTE CORONARY SYNDROME		
①	Acute coronary syndrome (ACS) is an umbrella term including unstable angina (UA) or acute myocardial infarction (MI) which consists of ST segment elevation MI (STEMI) and non–ST segment MI (NSTEMI). Diagnosis is based on patient presentation, electrocardiographic changes, and elevated cardiac biomarkers.	**Case 13-1 (Questions 1–5), Figures 13-1–13-4, Table 13-1**
②	Treatment objectives of ACS are to alleviate ischemic symptoms, restore blood flow to the infarct-related artery, arrest infarct expansion, and prevent mortality.	**Case 13-1 (Questions 6,7)** **Case 13-2 (Question 1)**
③	For both STEMI and NSTE-ACS, initial therapies may include oxygen, nitroglycerin (NTG), antiplatelet agents, β-blocker, angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB), and morphine sulfate.	**Case 13-1 (Questions 8–11, 14–17), Table 13-2**
STEMI		
①	Treatment objectives of STEMI are to restore coronary blood flow by administering a fibrinolytic or performing percutaneous coronary intervention (PCI). Treatment strategy depends on availability of catheterization laboratory and skilled staff, time of initial medical contact, and contraindication for a fibrinolytic agent.	**Case 13-1 (Questions 12, 13),** **Figure 13-5, Table 13-4**
②	Regardless of reperfusion strategy, patients should receive aspirin in addition to a $P2Y_{12}$ inhibitor.	**Case 13-1 (Questions 8–10), Figure 13-5, Table 13-5**
③	For patients receiving fibrinolytic therapy, unfractionated heparin (UFH), enoxaparin, or fondaparinux should also be initiated.	**Case 13-1 (Question 8, 11), Figure 13-5**
④	For patients receiving PCI, an anticoagulant strategy consisting of either UFH with or without a glycoprotein IIb/IIIa inhibitor or bivalirudin alone should be administered.	**Case 13-1 (Question 11), Figure 13-5, Table 13-6**
NSTE-ACS		
①	For an invasive strategy, a $P2Y_{12}$ inhibitor (clopidogrel, prasugrel, or ticagrelor), anticoagulant (UFH, enoxaparin, bivalirudin, or fondaparinux	**Case 13-2 (Question 2–5), Figure 13-6, Table 13-6**

with UFH) along with aspirin and/or a glycoprotein IIb/IIIa inhibitor is given before angiography.	
② For an ischemia-guided strategy, an anticoagulant (enoxaparin, fondaparinux, or UFH) along with dual antiplatelet therapy should be considered.	**Case 13-2 (Question 6),** **Figure 13-6**
LONG-TERM THERAPIES	
① Potential long-term therapies include a β-blocker; statin; aspirin; clopidogrel, prasugrel, or ticagrelor; ACE inhibitor or ARB; aldosterone antagonist; and sublingual NTG. Unless contraindicated, ACE inhibitors or ARBs should be given to those with a left ventricular ejection fraction of less than 40%, hypertension, diabetes, or chronic kidney disease.	**Case 13-3 (Questions 1–9),** **Table 13-2**
② Lifestyle modifications include smoking cessation, weight management through diet and exercise to reduce body weight by 10% if body mass index exceeds 25 kg/m^2, diabetic treatment to achieve a near-normal hemoglobin A_{1c}, and serum lipid control to achieve an optimal low-density lipoprotein concentration of 100 mg/dL or less.	**Case 13-3 (Question 10)**

ACUTE CORONARY DISEASE

Despite advances in medical intervention and pharmacotherapy, cardiovascular disease continues to be a leading killer in the United States. Acute coronary syndrome (ACS) is an umbrella term that includes patients who present with either unstable angina (UA) or acute myocardial infarction (AMI) which is further differentiated into ST segment elevation myocardial infarction (STEMI) or non–ST segment myocardial infarction (NSTEMI).[1–5] The terminology, non–ST segment elevation-ACS (NSTE-ACS) includes both UA and NSTEMI.[1] These two conditions are determined based upon the presence (NSTEMI) or absence (UA) of biomarkers associated with necrosis. The etiology of ACS originates from the erosion or rupture of an unstable plaque within the coronary artery leading to the formation of an occlusive or nonocclusive thrombus. Although NSTE-ACS and STEMI lead to hospitalization, patients presenting with STEMI are considered medical emergencies and warrant immediate intervention.[5] Today, the management of ACS is based on reperfusion and revascularization using both pharmacologic and nonpharmacologic interventions such as percutaneous coronary intervention (PCI) and coronary artery bypass grafting (CABG).[1–5] A committee composed of representatives from the American College of Cardiology (ACC) and the American Heart Association (AHA) periodically review the literature and publish practice guidelines to aid health care practitioners in selecting the most effective treatments for patients with ACS.[1–5] These guidelines consist of graded recommendations based on the weight and quality of the evidence. Although there are local variations in practice, these guidelines serve as the foundation for care of patients with ACS.

Epidemiology

According to AHA statistics, 652,000 hospital discharges in the United States were attributable to ACS as the primary diagnosis in 2010. Financially, the impact of ACS is also exceedingly high.[6] The cost of hospitalization for ACS is expensive and continues to rise. In terms of direct medical expenditures, ACS costs Americans more than $150 billion annually, with 60% to 75% of these costs related to hospital admission and readmission.[7–9] Approximately one-third of STEMI patients die within 24 hours of onset of ischemia compared with 15% of patients with NSTE-ACS who either die or experience reinfarction within 30 days of hospitalization.[10] Although these numbers are substantial, the risk-standardized 30-day in-hospital mortality for Medicare beneficiaries admitted for AMI have significantly dropped during the past decade.[11] In an analysis of Medicare data for all fee-for-service patients 65 years or older with a diagnosis of ACS, Krumholz et al. estimated that the length of hospitalization for STEMI/NSTE-ACS has decreased from 6.5 days in 1999 to 5.3 days in 2011. These trends may be reflective of application of evidence-based guidelines as well as aggressive treatment of hypertension and hypercholesterolemia.[11]

Pathophysiology

The majority of ACS results from occlusion of a coronary artery secondary to thrombus formation overlying a lipid-rich atheromatous plaque that has undergone fissuring or rupture (Fig. 13-1). Plaques that are susceptible to rupture have a thin fibrous cap, large fatty core, high content of inflammatory cells such as macrophages and lymphocytes, limited amounts of smooth muscle, and eccentric shape. Triggers such as surges in sympathetic activity with a sudden increase in blood pressure (BP), pulse rate, myocardial contractility, and coronary blood flow can lead to erosion, fissuring, or rupture of the fragile fibrous cap. Once ruptured, the thrombogenic components of the plaque consisting of collagen and tissue factor are exposed. This promotes activation of the platelet cascade, ultimately leading to the formation of a thrombus as well as ischemia in the corresponding myocardial area. The extent of intracoronary thrombosis and distal embolization determines the type of ACS (Fig. 13-1). In patients with UA, the coronary artery has enough blood flow such that the myocardial cells do not die. In patients with NSTEMI, there exists partial thrombotic occlusion with or without distal embolization or severe stenosis and some myocardial cells die. For STEMI, there exists total and persistent thrombotic occlusion leading to myocardial cell death.[12] Eighty percent of patients presenting with ACS have two or more active plaques.[12]

Most infarctions are located in a specific region of the heart and are described as such (e.g., anterior, lateral, inferior). Some patients exhibit permanent electrocardiographic (ECG) abnormalities (Q waves) after an AMI. In the past, patients with Q-wave infarctions were generally believed to have more extensive necrosis and a higher in-hospital mortality rate. Patients with a non–Q-wave infarct were believed to have a greater likelihood of experiencing postinfarction angina and early reinfarction. More recently these distinctions have come into question. Some cardiologists believe there is no difference in prognosis. The terminology has changed because most patients who have STEMI are treated emergently, preventing the development of Q waves. An anterior wall infarction carries a worse prognosis than an inferior or lateral wall infarction because it is more commonly associated with development of left ventricular (LV) failure and cardiogenic shock.

Clinical Presentation

An important part in establishing the diagnosis of ACS is obtaining the patient's "story," which can elicit crucial hallmark symptoms such as increasing the frequency of exertional angina or chest pain at rest, new-onset severe chest discomfort, or increasing angina with a duration exceeding 20 minutes. The pain is typically midline anterior chest discomfort that can radiate to the left arm, back, shoulder, or jaw, and may be associated with diaphoresis, dyspnea, nausea, and vomiting as well as unexplained syncope. Patients with STEMI will usually complain of unrelenting chest pain whereas patients with NSTE-ACS will present with either angina at rest, new-onset (2 months or less) angina, or chronic angina that increases in frequency, duration, or intensity. Presentation may differ by sex, age, and presence of various comorbidities. Men commonly complain of chest pain, whereas women often present with nausea and diaphoresis. Elderly patients may present with hypotension or cerebrovascular symptoms rather than chest pain. Additionally, onset of ACS does not occur at random, and many episodes appear to be triggered by external factors or conditions. MI occurs with increased frequency in the morning, particularly within the first hour after awakening; on Mondays; during winter months or colder days; and during emotional stress and vigorous exercise.[1–5]

The physical examination is important in guiding initial therapy. Signs of severe LV or right ventricular dysfunction may be present (see Chapter 14, Heart Failure). The patient may have severe hypertension as a result of pain or, conversely, may be hypotensive. Significant tachycardia (heart rate > 120 beats/minute) suggests a large area of damage. On cardiac auscultation, presence of a fourth heart sound (S_4) denotes an ischemia-induced decrease in LV compliance. New cardiac murmurs may be heard, resulting from papillary muscle dysfunction. The cerebral and peripheral vasculature should be assessed. Patients with a history of cerebrovascular disease may not be eligible for fibrinolytic therapy. Peripheral pulses should be examined to assess perfusion and to obtain a baseline before invasive procedures are instituted.

Diagnosis

In addition to the patient's history and presentation, the diagnosis of ACS is based on the electrocardiogram (ECG) and laboratory results from a cardiac injury profile. A 12-lead ECG should be obtained within 10 minutes of presenting to the emergency department (ED). The ECG is an indispensable tool in the diagnosis of ACS and has become the key point in the decision pathway (Fig. 13-2). Key findings on ECG consist of ST segment elevation, ST segment depression, or T-wave inversion.[1–5] By definition, STEMI consists of ST segment elevation in two or more contiguous leads and either exceeding 0.2 mV (2 mm) in leads V_1, V_2, and V_3 or 0.1 mV (1 mm) or greater in other leads (Fig. 13-3). NSTE-ACS consists of ST segment depression exceeding 0.1 mV (1 mm) in two or more contiguous leads or T-wave inversions exceeding 0.1 mV (1 mm). Additionally, the 12-lead ECG is helpful in determining the location of an infarct. Q waves may be found in lead V_6 for a posterior infarct; in leads II, III, AVF for an inferior infarct; in lead I, AVL for a lateral infarct; and in the precordial leads V_1, V_2, V_3, or V_4 for an anterior infarction.[13]

Laboratory Changes

When a cardiac cell is injured, proteins are released into the circulation. The measurement of these sensitive and specific proteins (troponins T or I and creatine kinase [CK]) is routine in establishing the diagnosis of AMI (Fig. 13-4). There are three isoenzymes of CK, of which the MB band is the most specific for the myocardium. Troponin is the preferred biomarker for assessment of myocardial damage owing to its high cardiac specificity and sensitivity (90.7% and 90.2%, respectively) as well as the development of newer sensitive troponin assays. Troponins T and I are detectable in blood within 4 to 12 hours after the onset of MI, and peak values are observed at 12 to 48 hours. Troponin levels may also stay elevated for 7 to 10 days after myocardial necrosis. As seen in Figure 13-4, the horizontal line depicts the upper reference limit (URL) for the cardiac biomarker in the clinical chemistry laboratory.[1,2,5] The URL represents the 99th percentile of a reference control group without MI. Because cardiac troponin T and I are not normally detected in the blood of healthy people, the definition of an abnormally increased level is a value that exceeds that of 99% of a reference control group. For the diagnosis of NSTEMI or STEMI, the patient should have one troponin value or two CK-MB values greater than the URL. Cardiac biomarkers are not typically elevated in patients with UA. Presently, no current marker is detectable immediately upon onset of MI, and therefore repeated measurements of cardiac enzymes after admission are warranted. A cardiac injury profile will be measured at presentation and every 3 to 6 hours for the first 12 to 24 hours and periodically thereafter.[2–4] Unfortunately, several conditions other than AMI, such as tachyarrhythmias, heart failure (HF), myocarditis and pericarditis, hypotension or hypertension, acute pulmonary embolism, end-stage renal disease and cardiac trauma are associated with elevated troponin. As a result, it is important to assess other diagnostic criteria such as ECG changes, chest pain, presence of atherosclerotic risk factors, and echocardiographic findings.

Figure 13-3 ECG changes related to STEMI. On this admission electrocardiogram (ECG), note the extensive ST segment elevation in leads II, III, and aV_F (brackets), indicating an inferior wall acute myocardial infarction (AMI). The patient also displays reciprocal ST segment depression in leads I and aV_L (arrows), which are the lateral ECG leads and are opposite the inferior leads.

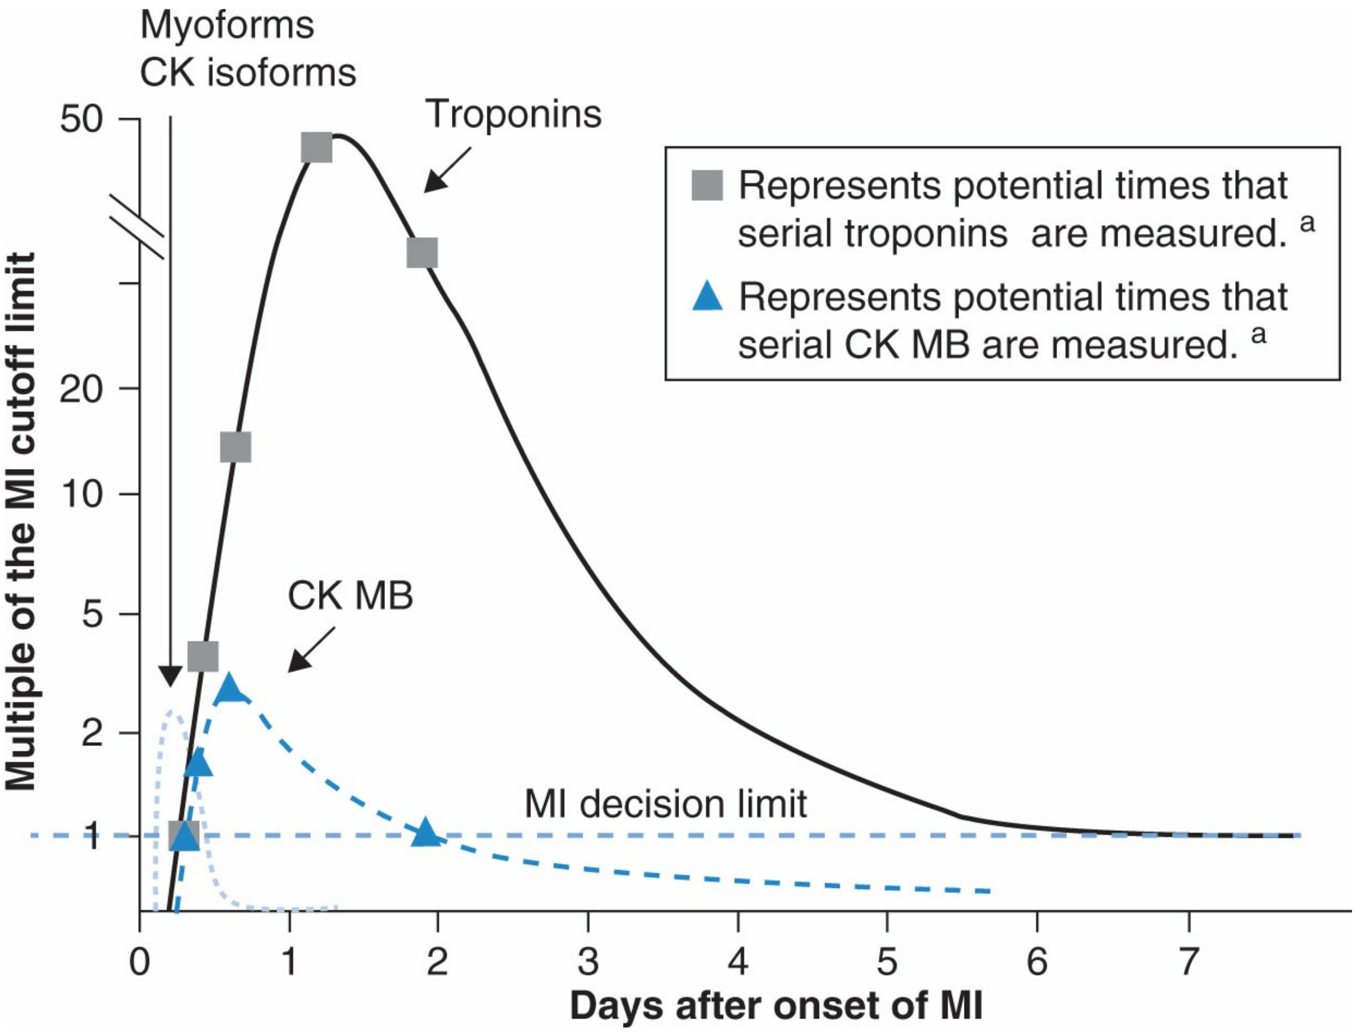

Figure 13-4 Cardiac biomarker elevation in acute coronary syndrome. CK, creatine kinase; MI, myocardial infarction. a. Serial troponins and CK-MB are initially measured during the first 12 to 24 hours of onset of chest pain and continued to be measured until the concentrations begin to decline. (Adapted with permission from Anderson JL et al. ACC/AHA 2007 guidelines for the management of patients with unstable angina/non-ST-Elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines for the Management of Patients With Unstable Angina/Non-ST-Elevation Myocardial Infarction) developed in collaboration with the American College of Emergency Physicians, the Society for Cardiovascular Angiography and Interventions, and the Society of Thoracic Surgeons endorsed by the American Association of Cardiovascular and Pulmonary Rehabilitation and the Society for Academic Emergency Medicine. J Am Coll Cardiol. 2007;50(7):e1–e157.)

Risk Stratification

The examination of a patient presenting with ACS begins with stratification for the risk of death and reinfarction, taking into account the presenting signs and symptoms, past medical history, ECG and cardiac biomarker changes. Patients can be stratified into low, medium, or high risk for mortality, and the need for urgent coronary angiography and PCI (Fig. 13-2). In 1967, Killip and Kimball introduced a useful, convenient tool for early risk stratification for patients with STEMI. Higher Killip class was found to be associated with increased in-hospital and 1-year mortality (Table 13-1).[14] The Thrombolysis in Myocardial Infarction (TIMI) risk score was introduced in 2000 and can be used with either STEMI or NSTE-ACS (Table 13-

1).[15,16] For STEMI, a higher risk score indicates a greater 30-day mortality rate. Patients with STEMI are at the highest risk of death and reinfarction, and initial treatment should proceed with immediate revascularization regardless of their risk stratification score. “Time is tissue,” means the sooner the thrombosed artery is opened, the lower the morality and greater amount of myocardium preserved. Reperfusion therapy should be initiated in all eligible patients with STEMI with symptom onset within the prior 12 hours. Primary PCI is the recommended method of reperfusion. The ACC/AHA guidelines define a target time to initiate reperfusion for STEMI within 30 minutes of hospital presentation for fibrinolytic therapy and within 90 minutes from presentation for PCI.[5]

In the case of NSTE-ACS, a TIMI risk score of 5 to 7, 3 to 4, and 0 to 2 reflect a high, moderate, and low risk for death, MI, or need for urgent coronary artery revascularization, respectively (Table 13-1). A low-risk patient with negative cardiac biomarkers may undergo a stress test or be discharged from the ED with a diagnostic test scheduled within 72 hours. Moderate and high-risk patients are often admitted to the hospital for pharmacologic treatment, further diagnostic tests, and angiography with possible intervention. Additional risk stratification tools such as the Platelet glycoprotein IIb/IIIa in Unstable angina: Receptor Suppression Using Integrilin Therapy (PURSUIT) risk score and Global Registry of Acute Cardiac Events (GRACE) risk score exist for in-hospital and 1-year morality.[1,5] Other risk scores are available to predict bleeding in patients with ACS.[17]

Complications

The primary complications of ACS can be divided into three major groups: pump failure, arrhythmias, and recurrent ischemia and reinfarction. Depression of cardiac function after AMI is related directly to the extent of LV damage. As a result of decreased cardiac output and decreased perfusion, a number of compensatory mechanisms become activated. The levels of circulating catecholamines increase in an attempt to increase contractility and restore normal perfusion. In addition, the renin-angiotensin-aldosterone system is enhanced, leading to an increase in systemic vascular resistance and sodium and water retention. These compensatory mechanisms can eventually worsen the imbalance between myocardial oxygen supply and consumption by increasing the myocardial oxygen demand.[18]

Table 13-1

Risk Stratification Tools for Acute Coronary Syndrome

TIMI Risk Score[a]

STEMI		**NSTE-ACS**	
Risk Factor	**No. of Points**	**Risk Factor**	**No. of Points**
Age 65–74 years	2	Age ≥ 65 years	1
Age ≥ 75 years	3	≥3 risk factors for CAD[b]	1
SBP < 100 mm Hg	3	Prior history of CAD[c]	1
Heart rate > 100 beats/minute	2	Aspirin use in past 7 days	1
Killip class II–IV	2	≥2 anginal events in past 24 hours	1
Weight < 67 kg	1	ST segment deviation ≥ 0.5 mm	1
History of HTN, diabetes, or angina	1	Elevation of cardiac markers[d]	1
Time to reperfusion therapy >4 hours	1		
Anterior ST segment elevation or left bundle branch block	1		

Killip Class[e]

Class	**Symptoms**	**In-Hospital and 1-Year Mortality (%)**
I	No heart failure	5
II	Mild heart failure, rales, S_3, congestion on chest radiograph	21
III	Pulmonary edema	35
IV	Cardiogenic shock	67

[a] TIMI risk score data from Antman EM et al. The TIMI risk score for unstable angina/non-ST elevation MI: a method for prognostication and therapeutic decision making. JAMA. 2000;284:835; Morrow DA et al. Application of the TIMI risk score for ST-elevation MI in the National Registry of Myocardial Infarction 3. JAMA. 2001;286:1356. A risk score is calculated by adding the total number of risk factors. Total points for STEMI are 0–14, in which risk scores of 0, 2, 4, 6, 7, and >8 correspond to a 30-day mortality rate of 0.8%, 2.2%, 7.3%, 16%, 23%, and 36%, respectively. Total points for NSTE-ACS are 0–7, in which scores of 0 or 1, 3, 5, and 7 correspond to a 3%, 5%, 12%, or 19% risk of death or repeat MI at 14 days, respectively. When risk stratifying, scores of 0 to 2, 3 to 4, and 5 to 7 represent low, moderate, and high risk for death or repeat MI at 14 days.

[b] Risk factors include smoking, diabetes, hypertension, family history of coronary artery disease, and hypercholesterolemia.

[c] Defined as a prior coronary stenosis ≥50%; history of previous myocardial infarction, percutaneous coronary intervention, or coronary artery bypass graft; or chronic stable angina pectoris associated with a positive exercise tolerance test or pharmacologically induced nuclear imaging or echocardiographic changes (positive nuclear imaging or echocardiographic changes required if female).

[d] Either troponin I or T or creatine kinase-MB.

[e] Killip class data from Killip T 3rd, Kimball JT. Treatment of myocardial infarction in a coronary care unit. A two year experience with 250 patients. Am J Cardiol. 1967;20:457.

CAD, coronary artery disease; HTN, hypertension; NSTE-ACS, non–ST segment elevation acute coronary syndrome; SBP, systolic blood pressure; STEMI, ST segment elevation myocardial infarction; TIMI, Thrombolysis in Myocardial Infarction.

Signs and symptoms of HF are common in patients who have abnormal wall motion affecting 20% to 25% of the LV. If 40% or more of the LV is damaged, cardiogenic shock and death may occur. Ischemia and scar formation after an AMI may lead to a decrease in ventricular compliance, resulting in abnormally high LV filling pressures during diastole. (See Chapter 14, Heart Failure, for further discussion on HF with reduced ejection fraction and preserved ejection fraction.)

Decreased contractility and a compensatory increase in LV end-diastolic volume and pressure lead to increased wall stress within the left ventricle. LV enlargement is an important determinant of mortality after AMI. During a period of days to months after an AMI, the infarcted area may expand as a result of dilatation and thinning of the LV wall. These changes are known as ventricular remodeling. In addition, hypertrophy of the noninfarcted myocardium occurs. Administration of oral angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), or aldosterone antagonists may limit remodeling and will attenuate the progression of LV dilatation.[19,20]

During the peri-infarction period, the heart is irritable and subject to ventricular arrhythmias. The continuous monitoring of patients in a coronary care unit has reduced the in-hospital mortality rate related to ventricular arrhythmias. However, patients who have had an AMI have an increased risk of sudden cardiac death for 1 to 2 years after hospital discharge. The most important predictor for sudden cardiac death is an abnormal LV ejection fraction (LVEF). Other factors associated with an increased risk for sudden cardiac death are complex ventricular ectopy, frequent (>10/hour) premature ventricular complexes, and the identification of late potentials on a signal-averaged ECG.[18]

OVERVIEW OF DRUG AND NONDRUG THERAPY

Overlap exists regarding the pharmacotherapy for both STEMI and NSTE-ACS. According to the ACC/AHA guidelines, early therapies should consist of oxygen (if oxygen saturation is <90%), sublingual

---

(SL) and/or intravenous (IV) nitroglycerin (NTG), IV morphine, ACE inhibitor or ARB, aldosterone antagonist, antiplatelet agents, stool softener, β-blocker, statin, and anticoagulant. Adjunctive therapies such as analgesics and vasodilators can also be considered in selected patients. Table 13-2 summarizes the evidence-based pharmacotherapies for both STEMI and NSTE-ACS. Figure 13-5 provides an initial treatment algorithm for patients with STEMI, and Figure 13-6, for patients with NSTE-ACS. Administration of these pharmacotherapies serves as a performance measure for health systems to ensure effective, timely, safe, and efficient patient-centered care.[1,5]

Fibrinolytic Drugs

Because the majority of STEMI cases result from the sudden occlusion of a coronary artery, the priority is to open the occluded artery as quickly as possible. This is accomplished by administering a fibrinolytic agent that enhances the body's own fibrinolytic system or by mechanically reducing the obstruction with PCI.[5]

Large clinical trials have proven that administration of a fibrinolytic agent reduces mortality. Early mortality from STEMI was reduced by approximately one-third (from 10%–15% to 6%–10%) with fibrinolytic therapy.[5]

The fibrinolytic drugs currently used for STEMI patients in the United States are alteplase (t-PA), reteplase (r-PA), and tenecteplase (TNK). Alteplase is a naturally occurring enzyme produced by recombinant DNA technology. It cleaves the same plasminogen peptide bond that urokinase cleaves. However, t-PA has a binding site for fibrin, which allows it to bind to and preferentially lyse thrombin-bound instead of circulating plasminogen. Reteplase is a genetically modified plasminogen activator that is similar to t-PA. Reteplase has a longer half-life, allowing it to be administered as two bolus injections 30 minutes apart, rather than as a bolus plus infusion. TNK is a genetically modified form of t-PA. Compared with t-PA, TNK has a longer plasma half-life, better fibrin specificity, and higher resistance to inhibition by plasminogen-activator inhibitor.[21,22] The pharmacologic properties and dosing regimens are compared in Table 13-3.

Unfortunately, an ideal fibrinolytic agent does not exist. Three problems common to all fibrinolytic drugs are the inability to open 100% of coronary artery occlusions, inconsistent ability to maintain good blood flow in the infarcted artery after it is opened, and bleeding complications. When assessing coronary artery flow after reperfusion therapy, the TIMI flow grade is used. Flow in coronary arteries is classified as grade 0 (no flow), grade 1 (penetration without perfusion), grade 2 (partial perfusion), or grade 3 (complete perfusion).[23] When assessing an episode of bleeding, the TIMI bleeding criteria are used. TIMI major bleeding consists of overt clinical bleeding or documented intracranial or retroperitoneal hemorrhage that is associated with a drop in hemoglobin of at least 5 g/dL or hematocrit of at least 15% (absolute). TIMI minor bleeding is defined as overt clinical bleeding associated with a fall in hemoglobin of 3 to 5 g/dL or in hematocrit of 9% to 15% (absolute).[24]

To minimize the risk of bleeding complications, contraindications to the use of fibrinolytic drugs must be evaluated before administration (Table 13-4). There are relatively few absolute contraindications to fibrinolytic therapy, but each patient should be assessed carefully to ascertain whether the potential benefit outweighs the potential risk. Because of the serious nature of intracerebral hemorrhage, patients should be selected carefully before receiving these agents. Generally, the diagnosis of STEMI must be ensured, with a history consistent with ischemia, and presence of ST segment elevation in two contiguous leads, or a new left bundle branch block on the ECG. Once the diagnosis is made, the fibrinolytic agent should be administered immediately if there are no contraindications.[5]

Fibrinolytic therapy is indicated in patients with STEMI who present to the hospital within 12 hours of symptom onset and are unable to undergo primary PCI within 120 minutes from first medical contact.[5] The benefit derived from fibrinolytic therapy is directly related to the time from the onset of chest pain to the time of administration. Although the guidelines recommend initiation within 12 hours from the onset of chest pain, data from clinical trials suggest that mortality reduction is greater when fibrinolytic therapy is initiated within 0 to 2 hours of symptom onset compared with treatment initiated more than 2 hours after symptoms have begun. The guidelines recommend a "door-to-needle time" of 30 minutes, meaning the diagnosis of STEMI and initiation of fibrinolytic therapy should ideally take place within 30 minutes from the time the patient arrives at the hospital door. Once stabilized, the patient should be transferred to a facility capable of PCI in case reperfusion fails or reocclusion occurs.[5]

In patients with NSTE-ACS, fibrinolytic agents are not recommended. Thrombi in this population are primarily platelet-rich rather than fibrin-rich, and less responsive to fibrinolytic therapy.[25] Additionally, data from the TIMI IIIB trials suggest that compared with placebo, alteplase was not associated with any improvement in death, MI, or failure of initial therapy and was associated with an increased incidence in fatal and nonfatal MI.[26]

Antiplatelet and Anticoagulant Drugs

When thrombolysis occurs, whether because of the administration of a fibrinolytic agent or through activation of the body's own fibrinolytic system, the fibrin clot begins to disintegrate. As the clot dissolves, there is a paradoxical increase in local thrombin generation and enhanced platelet aggregability, which may lead to rethrombosis. Antiplatelet agents (aspirin, $P2Y_{12}$ receptor antagonists: clopidogrel, prasugrel, or ticagrelor, and the glycoprotein [GP] IIb/IIIa inhibitors), as well as parenteral anticoagulants (unfractionated heparin [UFH], low-molecular-weight heparins [LMWH] such as enoxaparin, and direct thrombin inhibitors [DTIs] such as bivalirudin), have been used to minimize rethrombosis. UFH has several limitations, including a highly variable anticoagulant effect necessitating frequent monitoring and development of heparin-induced thrombocytopenia (<0.2%). LMWH may offer advantages compared with heparin owing to its ease of administration, improved bioavailability, and need for less monitoring. Unlike UFH, the DTIs offer better protection against thrombin reactivation after therapy discontinuation.

The GP IIb/IIIa receptor inhibitors, which are tirofiban, eptifibatide, and abciximab are also used. Glycoprotein IIb/IIIa receptors are abundant on the platelet surface. Platelets become activated when patients are having an acute ischemic event or are undergoing PCI. With platelet activation, the GP IIb/IIIa receptor undergoes a conformational change that increases its affinity for binding fibrinogen. The binding of fibrinogen to receptors on platelets results in platelet aggregation, leading to thrombus formation. The GP IIb/IIIa receptor inhibitors prevent platelet aggregation by preventing fibrinogen from binding to GP IIb/IIIa receptor sites on activated platelets.[5]

Acute thrombocytopenia is a rare but recognized side effect of all three agents, but seen more often with abciximab.[27] The GP IIb/IIIa inhibitors are used in conjunction with other antiplatelet drugs and anticoagulants in patients with NSTE-ACS and in patients undergoing PCI. Although effective when used in conjunction with fibrinolytic agents for patients with STEMI, the benefit is offset by high rates of bleeding. Therefore, routine use of GP IIb/IIIa inhibitors is not recommended with fibrinolytics.[5]

Table 13-2

Evidenced-based Pharmacotherapies for Acute Coronary Syndromes[1,5]

Drug	Indication	Dose and Duration	Therapeutic End Points	Precautions	Comments
ACE inhibitors[a]	STEMI and NSTE-ACS within the first 24 hours of presentation for those with EF ≤40% or s/s of HF STEMI and NSTE-ACS for late hospital care for patients with hypertension, EF ≤ 40%, DM, or CKD STEMI and NSTE-ACS for indefinite use for all patients with EF ≤40%.	Usual captopril dose 12–50 mg TID, then start longer-acting ACE inhibitor. Duration indefinite.	Titrate to usual doses and maintain systolic BP > 90 mm Hg.	Avoid IV therapy within 48 hours of infarct. Avoid initiation with systolic BP <100 mm Hg, pregnancy, acute renal failure, angioedema, bilateral renal stenosis, serum potassium ≥ 5.5 mEq/L.	
Angiotensin receptor blockers[a]	STEMI and NSTE-ACS with ACE inhibitor intolerance.	Usual doses of ARBs (see Chapter 14, Heart Failure). Duration indefinite.	Same as for ACE inhibitors.	Same as for ACE inhibitors.	

Aldosterone antagonists[a]	STEMI and NSTE-ACS with EF ≤40% and either DM or HF symptoms already receiving therapeutic doses of an ACE inhibitor and β-blocker.	Spironolactone 12.5–50 mg daily or eplerenone 25–50 mg daily. Duration indefinite.	Titrate to heart failure symptom control without evidence of hyperkalemia	Hyperkalemia, hypotension Avoid if potassium ≥ 5 mEq/L or SCr ≥ 2.5 mg/dL for men and 2.0 mg/dL for women or CrCl ≤30 mL/minute	Dose can be increased every 4–8 weeks.
Aspirin[a]	STEMI and NSTE-ACS for all patients.	162–325 mg during AMI, then 81–325 mg daily indefinitely (81 mg daily is preferred).		Active bleeding, thrombocytopenia	Unless clear contraindication exists, aspirin should be given to all AMI patients.
Amiodarone	Treatment of VT, VF.	150 mg IV over 10 minutes, repeat for recurrence, follow with 1 mg/minute IV infusion for 6 hours, then 0.5 mg/minute (maximum: 2.2 g/24 hours).	Cessation of arrhythmia.	Bradycardia, hypotension.	
β-Blockers[a]	STEMI and NSTE-ACS in all patients without contraindications.	Variable. Titrate to HR and BP. It is reasonable to administer an IV β-blocker at the time of presentation to STEMI patients who are hypertensive and who do not have any of the following: (a) signs of heart failure, (b) evidence of a low output state, (c) increased risk for cardiogenic shock[b], or (d) other relative contraindications to β-blockade (PR interval > 0.24 second, second- or third-degree heart block, active asthma, or reactive airway disease). Duration indefinite.	Titrate to resting HR approx. 60 beats/minute, maintain systolic BP >100 mm Hg.	Observe HR and BP closely when given IV Contraindicated in patients with HR <50 beats/minute; PR ECG interval >0.24 second, second- or third-degree heart block, persistent hypotension, pulmonary edema, bronchospasm, risk of cardiogenic shock, severe reactive airway disease.	Unless clear contraindication exists, β_1-selective agents such as metoprolol and atenolol should be given to all AMI patients. In patients with systolic dysfunction, metoprolol, carvedilol, or bisoprolol can be considered.

Bivalirudin[a]	STEMI with primary PCI and NSTE-ACS with an early invasive strategy.	STEMI with primary PCI: 0.75 mg/kg IV bolus immediately prior to PCI, followed by 1.75 mg/kg/hour infusion with or without UFH. NSTE-ACS with an early invasive strategy: 0.1 mg/kg IV bolus followed by 0.25 mg/kg/hour infusion. Continue until diagnostic angiography or PCI is performed.		Avoid in patients with active bleeding.	Reduce infusion to 1 mg/kg/hour with estimated CrCl <30 mL/minute.
Cangrelor[a]	STEMI and NSTE-ACS before PCI in patients not treated with a $P2Y_{12}$ platelet inhibitor and are not being given a GP IIb/IIIa inhibitor.	30 µg/kg IV bolus prior to PCI followed immediately by a 4 µg/kg/minute IV infusion for at least 2 hours or duration of procedure, whichever is longer		Active bleeding	After discontinuation of infusion, an oral $P2Y_{12}$ platelet inhibitor should be administered: ticagrelor 180 mg load during or upon immediate discontinuation of infusion; prasugrel 60 mg or clopidogrel 600 mg upon immediate discontinuation of infusion.
Calcium-channel blockers	STEMI and NSTE-ACS for patients with ongoing ischemia who are receiving adequate doses of nitrates and β-blockers. Consider diltiazem or verapamil for patients with contraindication to β-blocker if EF normal.	Usual doses of calcium-channel blockers are used. Duration dictated by clinical scenario.	Titrate to usual doses and maintain systolic BP >90 mm Hg	Usual calcium-channel blocker contraindications. Avoid nondihydropyridines in patients with pulmonary congestion or EF <40% or AV block.	In patients with normal EF, most calcium-channel blockers will exert beneficial effects. Some data support use of verapamil or diltiazem for non–Q-wave AMI.
Clopidogrel[a]	STEMI and NSTE-ACS for patients allergic	75 mg daily.		Active bleeding, thrombotic thrombocytopenia	

	to aspirin.			purpura (rare).	
Clopidogrel + aspirin[a]	STEMI with fibrinolytic therapy, before PCI after fibrinolytic therapy, or before primary PCI. NSTE-ACS for early invasive or ischemia-guided strategies.	STEMI with fibrinolytic therapy: 300 mg load, then continue 75 mg daily, and continue for up to 1 year; aspirin 162–325 mg on first day, then 81–325 mg daily indefinitely (81 mg daily is preferred).		Active bleeding, thrombotic thrombocytopenia purpura (rare), avoid loading dose in patients ≥75 years of age, discontinue at least 5 days for CABG.	Whether administered before fibrinolytic or PCI, clopidogrel + aspirin reduced CV death, MI, or ischemia at 30 days. The 600 mg load should be considered if a GP IIb/IIIa is not used.

		STEMI with fibrinolytic therapy with PCI: if PCI < 24 hours from fibrinolytic, then 300 mg load and for >24 hours from fibrinolytic, 600 mg load, then continue 75 mg daily if coronary stent deployed for at least 1 year; aspirin 162–325 mg on first day, then 81–325 mg daily indefinitely (81 mg is preferred). STEMI before primary PCI: 600 mg load, then continue 75 mg daily if coronary stent deployed for at least 1 year; aspirin 162–325 mg on first day, then 81–325 mg/day indefinitely. (81 mg daily is preferred.) NSTE-ACS for early invasive or ischemia-guided strategy: 300–600 mg load, then continue 75 mg daily for at least 1 year; aspirin 162–325 mg on first day, then 81–325 mg/day indefinitely. (81 mg daily is preferred).			
Enoxaparin[a]	STEMI (as an alternative for UFH) for	STEMI with fibrinolytic therapy: Age <75 years, administer 30 mg IV bolus		Avoid in patients with active bleeding,	For CrCl 15–29 mL/minute reduce to 1

	patients receiving fibrinolytic therapy or for those not undergoing PCI. NSTE-ACS for early invasive or ischemia-guided strategies.	followed by 1 mg/kg SQ every 12 hours (max dose of 100 mg for patients weighing ≥100 kg). Age ≥75, administer 0.75 mg/kg SQ every 12 hours (first two doses administer max dose of 75 mg for patients weighing ≥75 kg). Continue up to 8 days or until revascularization. NSTE-ACS for early invasive or ischemia-guided strategies: 1 mg/kg SQ every 12 hours. A supplemental 0.3 mg/kg IV dose should be administered at the time of PCI if the last dose of SC enoxaparin was given 8–12 hours before PCI. Continue for duration of hospitalization or until PCI.		history of HIT, planned CABG, SCr ≥ 2.5 mg/dL in men and ≥2.0 mg/dL in women, or CrCl <15 mL/minute.	mg/kg every 24 hours.

Fibrinolytic therapy[a]	STEMI presenting within 12 hours after onset of symptoms, can be considered in patients presenting within 12–24 hours after onset of symptoms with continuing s/s of ischemia.	See Table 13-3.	Improved TIMI grade flow.	See Table 13-4.	
Fondaparinux[a]	STEMI: alternative for UFH or LMWH in patients receiving fibrinolytic therapy or in those not undergoing PCI. NSTE-ACS: alternative for UFH or LMWH for early invasive	STEMI: 2.5 mg SQ daily starting on day 2 of hospitalization, continue for 8 days or until revascularization. NSTE-ACS for early invasive or ischemia-guided strategies: 2.5 mg SQ daily for the duration of the hospitalization or until PCI is performed.		Avoid with active bleeding or CrCl < 30 mL/minute.	In STEMI, fondaparinux reduced mortality and reinfarction without increased bleeding or strokes compared with UFH, but only in patients not undergoing

	or ischemia-guided strategies. Administer additional anticoagulant with factor IIa activity in patients undergoing PCI.				PCI. In NSTE-ACS, fondaparinux was at least as effective as enoxaparin but exhibited less bleeding. Can possibly be used in HIT.
GP IIb/IIIa inhibitors[a]	STEMI: in patients undergoing PCI. NSTE-ACS: in patients treated with early invasive strategy and DAPT with intermediate/high-risk features.	See Table 13-6.		Avoid with active bleeding, thrombocytopenia, prior stroke.	In NSTE-ACS eptifibatide or tirofiban are FDA approved for PCI and ischemia-guided therapy. Abciximab is only for patients undergoing PCI.
Heparin[a]	STEMI: for patients undergoing PCI or treated with fibrinolytic therapy. NSTE-ACS: for early invasive or ischemia-guided strategies.	STEMI with fibrinolytic therapy or NSTE-ACS with early invasive or ischemia-guided strategies: 60 units/kg IV bolus (max 4,000 units) followed by 12 units/kg/hour (max 1,000 units/hour) for 48 hours or until revascularization. STEMI with PCI: 50–70 units/kg IV bolus if a GP IIb/IIIa inhibitor planned; or 70–100 units/kg IV bolus if no GP IIb/IIIa inhibitor. Continue for 48 hours or until end of PCI.	aPTT ratio 1.5–2.5× patient's control value, aPTT should be obtained 4–6 hours after initiation of infusion if not treated with fibrinolytic therapy or PCI and within 3 hours if treated with fibrinolytic therapy.	Avoid with active bleeding, thrombocytopenia, recent stroke.	Unless clear contraindication exists, UFH should be given to all AMI patients who do not receive fibrinolytic therapy.
Morphine and other analgesics	STEMI and NSTE-ACS for patients whose symptoms not relieved by NTG or adequate anti-ischemic therapy.	Morphine: 2–5 mg IV every 5–30 minutes PRN.	Decreased chest pain and HR.	Avoid morphine with bradycardia, right ventricular infarct, hypotension, confusion.	Has been associated with higher risk of death; discontinue nonselective NSAIDs and COX-2 selective agents.

Nitroglycerin[a]	STEMI and NSTE-ACS with persistent ischemia, hypertension, or pulmonary congestion.	Variable; titrate to pain relief or systolic BP: 5–10 mcg/minute titrated to 200 mcg/minute. Usually maintain IV therapy for 24–48 hours after infarct.	Titrate to pain relief or systolic BP > 90 mm Hg	Avoid with systolic BP < 90 mm Hg, right ventricular infarction, sildenafil or vardenafil within 24 hours, or tadalafil within 48 hours.	Use acetaminophen or narcotics for headache. NTG should be tapered gradually in ischemic heart disease patients. Topical patches or oral nitrates are useful for patients with refractory symptoms.
Prasugrel + Aspirin[a]	STEMI: before PCI after fibrinolytic therapy or before primary PCI. NSTE-ACS: before PCI with coronary stenting.	60 mg loading dose, then 10 mg daily (if ≥60 kg) or 5 mg (if <60 kg) if coronary stent deployed for at least 1 year; aspirin 162–325 mg on day 1, then 81–325 mg daily indefinitely (81 mg daily is preferred).		Avoid with active bleeding, prior stroke or TIA, age ≥75 years Do not start if urgent CABG needed; discontinue 7 days before elective CABG or other surgery.	
Ticagrelor + Aspirin[a]	ACS: previous history of AMI STEMI: before primary PCI. NSTE-ACS: for early invasive or ischemia-guided strategies.	ACS with previous history of MI: Load with 180 mg oral loading dose following an ACS event, then continue treatment with 90 mg twice daily during the first year after an ACS event. After 1 year, administer 60 mg twice daily; aspirin 162–325 mg on day 1, then 81 mg daily indefinitely. STEMI before primary PCI:180 mg load, then continue 90 mg BID if coronary stent deployed for at least 1 year; aspirin 162–325 mg on day 1, then 81 mg daily indefinitely. NSTE-ACS with early	No firm end points	Avoid in patients with severe hepatic impairment or active bleeding. Maintenance doses of aspirin above 100 mg daily can decrease ticagrelor's effectiveness, Discontinue at least 5 days prior to CABG.	Monitor closely for dyspnea. For at least the first 12 months following ACS, ticagrelor was found to be superior to clopidogrel. Maximum dose of simvastatin is 40 mg with ticagrelor.

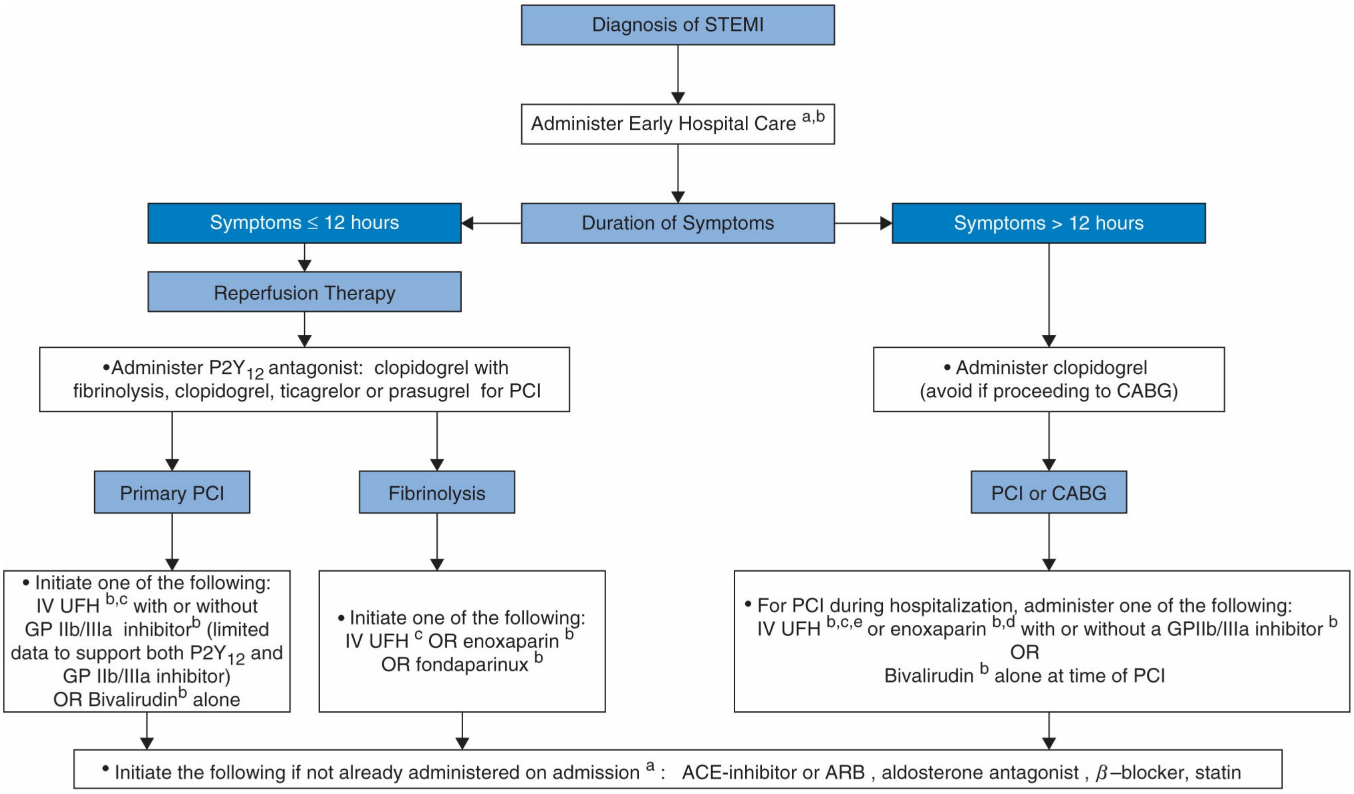
		invasive or ischemia-guided strategy: 180 mg load, then continue 90 mg BID if coronary stent deployed or for both early invasive or ischemia-guided strategies for at least 1 year; aspirin 162–325 mg on day 1, then 81 mg daily indefinitely.			

Vorapaxar	ACS for secondary prevention of thrombotic cardiovascular events.	1 tablet (2.08 mg) daily.		Contraindicated in history of stroke, TIA, ICH, or active bleeding.	Use with aspirin and/or clopidogrel according to their indications or standard of care. No data with ticagrelor or prasugrel or as use as a single antiplatelet agent.
Warfarin	STEMI and NSTE-ACS for left ventricular thrombus or for patients with AF with CHA_2DS_2VASc score ≥ 2.	Variable; titrate to INR. Duration usually dependent upon indication for warfarin.	INR goal 2–3. If receiving DAPT, then consider INR goal to 2.0–2.5 or discontinue aspirin.	Usual warfarin problems such as noncompliance and bleeding diathesis.	May be useful in the presence of a left ventricular thrombus or atrial fibrillation to prevent embolism.

ACE, angiotensin-converting enzyme; AF, atrial fibrillation; AMI, acute myocardial infarction; aPTT, activated partial thromboplastin time; ARBs, angiotensin receptor blockers; BID, twice daily; BP, blood pressure; CABG, coronary artery bypass graft; CHA_2DS_2VASc, risk score for atrial fibrillation comprising age, sex, HF, hypertension, stroke/TIA/thromboembolism, vascular disease, and DM; CKD, chronic kidney disease; CNS, central nervous system; COX-2, cyclooxygenase-2; CrCl, creatinine clearance; CV, cardiovascular; DAPT, dual antiplatelet therapy; DM, diabetes mellitus; ECG, electrocardiogram; EF, ejection fraction; FDA, Food and Drug Administration; GP IIb/IIIa, glycoprotein IIb/IIIa inhibitor; HF, heart failure; HIT, heparin-induced thrombocytopenia; HR, heart rate; INR, international normalized ratio; ICH, intracranial hemorrhage; IV, intravenous; LMWH, low-molecular-weight heparin; MI, myocardial infarction; NSAIDs, nonsteroidal antiinflammatory drugs; NSTE-ACS, non–ST segment elevation acute coronary syndrome; NTG, nitroglycerin; PCI, percutaneous coronary intervention; PRN, as needed; SCr, serum creatinine; SQ, subcutaneously; s/s, signs and symptoms; STEMI, ST segment elevation myocardial infarction; TIA, transient ischemic attack; TID, 3 times a day; TIMI, Thrombolysis in Myocardial Infarction; UHF, unfractionated heparin; VF, ventricular fibrillation; VT, ventricular tachycardia.

[a] Indicates specific drug therapies that are known to reduce morbidity or mortality.

[b] Risk factors for cardiogenic shock (the greater the number of risk factors present, the higher the risk of developing cardiogenic shock) are age >70 years, systolic BP < 120 mm Hg, sinus tachycardia >110 beats/minute, or HR < 60 beats/minute.



Diagnosis of STEMI
Administer Early Hospital Care a,b
Duration of Symptoms
Symptoms ≤ 12 hours
Symptoms > 12 hours
Reperfusion Therapy
•Administer P2Y12 antagonist: clopidogrel with fibrinolysis, clopidogrel, ticagrelor or prasugrel for PCI
• Administer clopidogrel (avoid if proceeding to CABG)
Primary PCI
Fibrinolysis
PCI or CABG
• Initiate one of the following: IV UFH b,c with or without GP IIb/IIIa inhibitor b (limited data to support both P2Y12 and GP IIb/IIIa inhibitor) OR Bivalirudin b alone
• Initiate one of the following: IV UFH c OR enoxaparin b OR fondaparinux b
• For PCI during hospitalization, administer one of the following: IV UFH b,c,e or enoxaparin b,d with or without a GPIIb/IIIa inhibitor b OR Bivalirudin b alone at time of PCI
• Initiate the following if not already administered on admission a : ACE-inhibitor or ARB , aldosterone antagonist , β–blocker, statin

Figure 13-5 Initial treatment algorithm for STEMI. a: Early hospital care consists of oxygen for oxygen saturation $<90\%$, SL nitroglycerin, IV nitroglycerin, IV morphine, **β**-blocker, ACE inhibitor or ARB, aldosterone antagonist, stool softener, and statin. b: Refer to Table 13-2 for indications, dosing, and contraindications. c: For at least 48 hours. d: For the duration of the hospitalization, up to 8 days. ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; CABG, coronary artery bypass graft; GP IIb/IIIa, glycoprotein IIB/IIIA; NTG, nitroglycerin; O_2, oxygen; PCI, percutaneous coronary intervention; SL, sublingual; STEMI, ST segment elevation myocardial infarction; UFH, unfractionated heparin. The $P2Y_{12}$ receptor antagonists, ticagrelor, prasugrel, and clopidogrel, have evolved to become an integral part in the management of ACS. By blocking the $P2Y_{12}$ adenosine diphosphate receptors, these agents decrease platelet activation and aggregation, increase bleeding time, and reduce blood viscosity.[1–5] Differences in antiplatelet potency, pharmacokinetics, pharmacodynamics, pharmacogenomics, and drug–drug interactions exist between the three agents (Table 13-5). Cangrelor is an intravenous agent recently approved to reduce the risk of thrombotic events in patients undergoing PCI. It is for patients who are not being treated with another $P2Y_{12}$ inhibitor or a GP IIb/IIIa inhibitor.[28] Compared with the oral agents, cangrelor has a very rapid onset (2 minutes) and offset of action (1 hour).[28] In the Cangrelor versus Standard Therapy to Achieve Optimal Management of Platelet Inhibition (CHAMPION) PHOENIX trial, the primary composite end point of death, MI, ischemia-driven revascularization, or stent thrombosis at 48 hours occurred in significantly fewer patients treated with IV cangrelor compared to oral clopidogrel (4.7% vs. 5.9%, $p = 0.005$). Although the benefit persisted at 30 days, it came at the expense of an increase in bleeding with rates of about one in 170 with cangrelor versus one in 275 with clopidogrel.[29] Controversy surrounds the use of pharmacogenomic and platelet function testing when determining whether a patient may be a “responder” or “nonresponder” to clopidogrel therapy.[30]At this time, the ACC/AHA guidelines do not recommend routine testing for genetic variants. See Chapter 12, Chronic Stable Angina, for greater detail about these controversies.

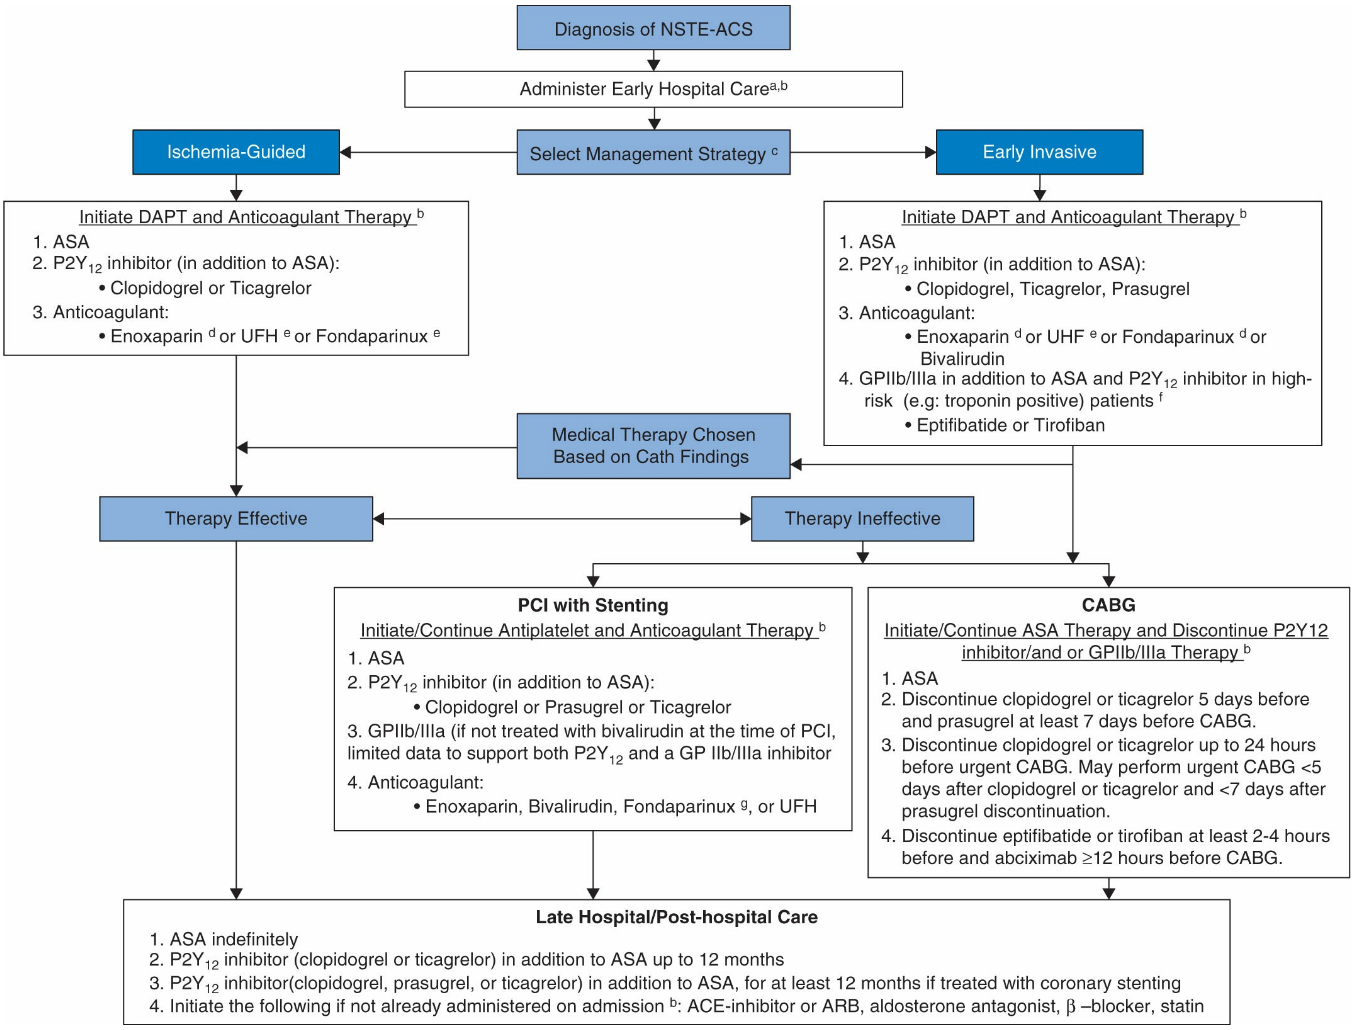
Vorapaxar is an oral antiplatelet that selectively inhibits the cellular actions of thrombin through antagonism of platelet protease-activated receptor-1. It is indicated for secondary prevention of cardiovascular events in patients who have a history of MI or peripheral vascular disease. In the Thrombin-Receptor Antagonist in Secondary Prevention of Atherothrombotic Ischemic Events (TRA2P–TIMI50) trial, patients with a history of MI, ischemic stroke, or peripheral arterial disease who received vorapaxar 2.5 daily had 13% reduction in the combined end point of death from cardiovascular causes, MI, or stroke ($p < 0.001$) and a 12% reduction in the combined end point of cardiovascular death, MI, stroke, or recurrent ischemia leading to revascularization ($p = 0.001$) compared to placebo.[31] However, patients receiving vorapaxar had an increase in moderate and severe bleeding including intracranial hemorrhage. Among patients with a history of stroke, the rate of intracranial hemorrhage in the vorapaxar group was 2.4% versus 0.9% with placebo ($p < 0.001$). About 67% of patients had a history of MI and of these 98% were receiving concomitant aspirin and 78% a $P2Y_{12}$ inhibitor.[31] Only 0.2% of patients received prasugrel and no patients received ticagrelor.[32] When considered for secondary prevention of thrombotic cardiovascular events in combination with aspirin and/or clopidogrel, vorapaxar is contraindicated in those with a history of stroke, transient ischemic attack, or intracranial hemorrhage.



Diagnosis of NSTE-ACS
Administer Early Hospital Care^{a,b}
Select Management Strategy ^{c}
Ischemia-Guided
Early Invasive
Medical Therapy Chosen Based on Cath Findings
Therapy Effective
Therapy Ineffective

Initiate DAPT and Anticoagulant Therapy ^{b}
1. ASA
2. P2Y$_{12}$ inhibitor (in addition to ASA):
   - Clopidogrel or Ticagrelor
3. Anticoagulant:
   - Enoxaparin ^{d} or UFH ^{e} or Fondaparinux ^{e}

Initiate DAPT and Anticoagulant Therapy ^{b}
1. ASA
2. P2Y$_{12}$ inhibitor (in addition to ASA):
   - Clopidogrel, Ticagrelor, Prasugrel
3. Anticoagulant:
   - Enoxaparin ^{d} or UHF ^{e} or Fondaparinux ^{d} or Bivalirudin
4. GPIIb/IIIa in addition to ASA and P2Y$_{12}$ inhibitor in high-risk (e.g: troponin positive) patients ^{f}
   - Eptifibatide or Tirofiban

PCI with Stenting

Initiate/Continue Antiplatelet and Anticoagulant Therapy ^{b}
1. ASA
2. P2Y$_{12}$ inhibitor (in addition to ASA):
   - Clopidogrel or Prasugrel or Ticagrelor
3. GPIIb/IIIa (if not treated with bivalirudin at the time of PCI, limited data to support both P2Y$_{12}$ and a GP IIb/IIIa inhibitor
4. Anticoagulant:
   - Enoxaparin, Bivalirudin, Fondaparinux ^{g}, or UFH

CABG

Initiate/Continue ASA Therapy and Discontinue P2Y12 inhibitor/and or GPIIb/IIIa Therapy ^{b}
1. ASA
2. Discontinue clopidogrel or ticagrelor 5 days before and prasugrel at least 7 days before CABG.
3. Discontinue clopidogrel or ticagrelor up to 24 hours before urgent CABG. May perform urgent CABG <5 days after clopidogrel or ticagrelor and <7 days after prasugrel discontinuation.
4. Discontinue eptifibatide or tirofiban at least 2-4 hours before and abciximab ≥12 hours before CABG.

Late Hospital/Post-hospital Care
1. ASA indefinitely
2. P2Y$_{12}$ inhibitor (clopidogrel or ticagrelor) in addition to ASA up to 12 months
3. P2Y$_{12}$ inhibitor(clopidogrel, prasugrel, or ticagrelor) in addition to ASA, for at least 12 months if treated with coronary stenting
4. Initiate the following if not already administered on admission ^{b}: ACE-inhibitor or ARB, aldosterone antagonist, β –blocker, statin

Figure 13-6 Initial treatment algorithm for NSTE-ACS. a: Early hospital care consists of oxygen for oxygen saturation <90%, SL nitroglycerin, IV nitroglycerin, IV morphine, β-blocker, ACE inhibitor or ARB, aldosterone antagonist, stool softener, and statin. b: Refer to Table 13-2 for indications, dosing, and contraindications. c: An early invasive strategy would be considered if one or more of the following occurs: recurrent angina or ischemia at rest, presence of elevated cardiac biomarkers, new or presumably new ST segment depression, signs or symptoms of HF or new worsening mitral regurgitation, hemodynamic instability, sustained ventricular tachycardia, PCI within 6 months, prior CABG, considered high risk per TIMI or GRACE risk score, LVEF < 40%. An ischemia-guided conservative strategy would be considered if the patient is classified as low-moderate risk per the TIMI or GRACE risk score or if the patient or clinician prefers this approach in the absence of high-risk features. d: For the duration of the hospitalization, up to 8 days. e: For at least 48 hours. f: Factors favoring administration of a GP IIb/IIIa in addition to a ASA and a P2Y^{12} inhibitor are delay to angiography, high-risk features, and early recurrent ischemia. g: In patients who have been treated with fondaparinux (as upfront therapy) who are undergoing PCI, an additional anticoagulant with anti-IIa activity should be administered at the time of PCI due to the risk of catheter thrombosis. ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; ASA, aspirin; CABG, coronary artery bypass graft; Cath, catheterization; DAPT, dual antiplatelet therapy; GP IIb/IIIa, glycoprotein IIb/IIIa; HF, heart failure; GRACE, Global Registry of Acute Coronary Events; IV, intravenous; NSTE-ACS, non–ST segment elevation acute coronary syndrome; PCI, percutaneous coronary intervention; SL, sublingual; TIMI, Thrombolysis in Myocardial Infarction; UFH, unfractionated heparin. (Adapted with permission from Amsterdam et al. AHA/ACC 2014 guidelines for the management of patients with unstable angina/non-ST-elevation acute coronary syndromes: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines developed in collaboration with the Society for Cardiovascular Angiography and Interventions and the Society of Thoracic Surgeons endorsed by the American Association of Thoracic Surgeons. J Am Coll Cardiol. 2014;64:e1–e228.)

Table 13-3

Pharmacologic Properties of Approved Fibrinolytic Drugs[22]

Drug	Fibrin Specificity	Potential Antigenicity	TIMI Grade Flow at 90 Minutes (% of Patients)	Average Dose	Dosing Administration	Cost
Alteplase	Moderate	No	54	100 mg	15 mg IV bolus, 50 mg for 30 minutes, then 35 mg for 60 minutes[a]	High
Reteplase	Moderate	No	60	10 + 10 units	10 U IV bolus, second bolus 30 minutes later	High
Tenecteplase	High	No	63	30–50 mg (based on weight)[b]	Bolus for 5–10 seconds	High

IV, intravenous; TIMI, Thrombolysis in Myocardial Infarction.

[a] For patients = 65 kg; reduced doses for patients weighing <65 kg.

[b] For patients <60 kg, 30 mg; 60–69 kg, 35 mg; 70–79 kg, 40 mg; 80–89 kg, 45 mg; 90 kg, 50 mg.

Table 13-4

Risk Factors Associated with Bleeding Complications Secondary to Fibrinolytic Use[5]

Absolute Contraindications
Any prior intracranial hemorrhage
Known structural cerebral vascular lesion (e.g., arteriovenous malformation)
Known malignant intracranial neoplasm (primary or metastatic)
Active bleeding or bleeding diathesis (excluding menses)
Suspected aortic dissection
Significant closed-head or facial trauma within 3 months
Intracranial or intraspinal surgery within 2 months
Ischemic stroke within 3 months, EXCEPT acute ischemic stroke within 4.5 hours
Severe uncontrolled hypertension (unresponsive to emergency therapy)
Uncontrolled hypertension on presentation (SBP > 180 mm Hg, DBP > 110 mm Hg)
Chronic, severe, poorly controlled hypertension
Prior ischemic stroke > 3 months, dementia, or known intracranial pathology
Puncture of a noncompressible vessel
Major surgery (<3 weeks)
Recent internal bleeding within 2–4 weeks

Active peptic ulcer Current use of anticoagulants (the higher the INR, the greater the risk for bleeding) Pregnancy

DBP, diastolic blood pressure; INR, international normalized ratio; SBP, systolic blood pressure.

β-Blockers

β-Blockers should be administered to patients with ACS unless a contraindication is present. In patients with ACS receiving either fibrinolytic therapy or PCI, β-blockers significantly decreased the rates of cardiovascular mortality, recurrent nonfatal MI, and all-cause mortality.[1–5] The 2014 ACC/AHA guidelines recommend that oral β-blocker therapy be initiated within 24 hours after the onset of symptoms for all patients without signs of HF, evidence of low output state, increased risk for cardiogenic shock or other contraindications. Both β-selective and nonselective agents have been evaluated; however, β-blockers with intrinsic sympathomimetic activity should be avoided as they lack efficacy data. For patients with tachycardia or hypertension without signs of HF, IV β-blockers followed by oral administration can be considered. Unless there are contraindications to their use, β-blocking agents should be prescribed for all patients after an AMI, and should be continued indefinitely.[5]

Table 13-5

Comparison of $P2Y_{12}$ Receptor Inhibitors[1,5,104]

Parameter	Clopidogrel	Prasugrel	Ticagrelor	Cangrelor
Class	Thienopyridine (second generation)	Thienopyridine (third generation)	Cyclopetyl triazolopyrimidine	Stabilized ATP analogue
Administration	Oral	Oral	Oral	Intravenous
Dose	300–600 mg LD 75 daily	60 mg LD 10 mg daily	180 mg LD 90 mg BID (60 mg BID for years 1–3)	30 µg/kg bolus 4 µg/kg/minute infusion
Age	–	If >75 years, not recommended unless history of DM or MI	–	–
Weight	–	If < 60 kg consider 5 mg daily	–	–

ATP, adenosine diphosphate; CABG, coronary artery bypass graft; CYP, cytochrome P450; LD, loading dose; BID, twice daily; ACS, acute coronary syndrome; NSTEMI, non–ST elevation myocardial infarction; STEMI, ST-elevation myocardial infarction; MI, myocardial infarction; PAD, peripheral arterial disease; NSTE-ACS, non–ST elevation acute coronary syndrome; PCI, percutaneous coronary intervention; NA, not applicable; NSAIDs, nonsteroidal antiinflammatory drugs; PPIs, proton-pump inhibitors; TIA, transient ischemic attack.

Statins

β-Hydroxy-β-methylglutaryl-CoA (HMG-CoA) reductase inhibitors (statins) reduce long-term morbidity and mortality in patients with cardiovascular disease. Beyond their lipid-lowering properties, statins are believed to exhibit pleiotropic effects, which include plaque stabilization, anti-inflammation, antithrombogenicity, enhancement of arterial compliance, and modulation of endothelial function.[33] Data regarding early intensive statin therapy in patients with STEMI or NSTE-ACS exist with atorvastatin, simvastatin, pravastatin, rosuvastatin, and fluvastatin.[1,5,34] Recent ACC/AHA cholesterol guidelines shift away from specific low-density lipoprotein (LDL) targets, instead advocating for fixed doses of statins to reduce cardiovascular risk. Following an AMI, patients should receive a high-intensity statin such as atorvastatin 40 to 80 mg or rosuvastatin ≥ 20 mg daily. Lower doses could be considered in patients > 75 years of age or those unable to tolerate higher doses[34] (see Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease).

Vasodilators

Other strategies for minimizing myocardial damage include the use of vasodilators in the peri-infarction period. Progressive LV dilatation ("remodeling") occurs in some patients after an AMI and has become an important marker for prognosis. Vasodilators reduce oxygen demand and myocardial wall stress by reducing afterload or preload and can attenuate the remodeling process. Some vasodilators may increase the blood supply to the myocardium by enhancing coronary vasodilatation.[1,5]

ACE inhibitors have been assessed in a large number of clinical trials, and all trials using oral agents have demonstrated a reduction in mortality.[1,5] Intravenous ACE inhibitors should be avoided because they cause excessive hypotension and do not improve survival. The benefit of ACE inhibitors is greatest in patients with anterior infarction, signs of HF, or a history of previous infarction. Ideally, oral ACE inhibitors should be started within 24 hours of diagnosis, after BP and renal function have stabilized. Initial doses should be low and then titrated as quickly as possible.[1,5] The ACC/AHA guidelines recommend an ARB in patients with ACS who cannot tolerate ACE inhibitors. The combination of an ACE inhibitor and ARB should be avoided because of an increase in adverse events such as hyperkalemia.

Aldosterone antagonists such as spironolactone and eplerenone have been associated with improved LV structural remodeling and performance by increasing LVEF and decreasing LV end-diastolic and end-systolic volumes. In the Eplerenone Post Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS), patients with AMI and LV dysfunction (LVEF < 40%) with or without HF were randomized 3 to 14 days after AMI to receive eplerenone (a selective aldosterone blocker). Eplerenone was found to decrease long-term mortality as an adjunct to ACE inhibitors and β-blockers.[35] Aldosterone blockade is recommended in post-MI patients with a LVEF < 40%, diabetes or symptoms of HF, assuming they have no contraindications.[1]

Nitrates dilate venous capacitance vessels and peripheral arterioles. Their predominant effect is a decrease in preload, with a lesser effect on afterload. Consequently, nitrates lead to a decrease in both myocardial wall stress and oxygen demand. Intravenous NTG should be used in patients who have refractory ischemic discomfort (chest pain), acute HF, and/or hypertension. Hemodynamic targets are a systolic BP between 100 and 130 mm Hg with a heart rate less than 100 beats/minute.

Other vasodilators that have been investigated in the treatment of ACS are the calcium-channel blockers. There are several proposed mechanisms whereby a calcium-channel blocker might be beneficial. As a group, they dilate coronary and peripheral vessels. They also alleviate some of the coronary vasospasm present at the time of coronary thrombosis. In addition, they are effective anti-ischemic agents through their action in improving coronary blood supply and reducing myocardial oxygen demand.[1,5]

The ACC/AHA guidelines recommend calcium-channel blockers for patients with persistent or recurrent symptoms after treatment with full-dose nitrates and β-blockers, for patients with contraindications to β-blockade, and for patients with Prinzmetal or variant angina. For such patients, calcium-channel blockers that slow the heart rate (e.g., diltiazem or verapamil) are recommended. These nondihydropyridines should not be administered to patients with severe LV dysfunction or pulmonary edema. The Danish Verapamil Infarction Trial (DAVIT) evaluated the efficacy of verapamil for patients with ACS.[36] There was a trend toward lower MI and mortality rates when verapamil was given to patients with suspected ACS. Similar reductions in MI and refractory angina rates have been demonstrated with diltiazem.[37] The dihydropyridine calcium antagonists amlodipine and felodipine have not been evaluated specifically for administration to patients with ACS, but trials involving normotensive patients with coronary artery disease (CAD) or hypertensive patients with cardiovascular risk factors have demonstrated that these agents provide significant benefits in reducing cardiovascular events.[38,39]

Analgesics

It is important to abolish the patient’s pain as quickly as possible because pain and anxiety associated with an AMI will contribute to increased myocardial oxygen demand. If the pain is not relieved by medications (e.g., nitrates, β-blockers), then additional analgesia may be necessary. Morphine sulfate (2 to 4 mg IV with increments of 2 to 8 mg IV repeated at 5 to 15 minute intervals) is the analgesic of choice for management of pain associated with STEMI. In addition to diminishing pain and anxiety, morphine also has beneficial hemodynamic effects. By reducing pain and anxiety, the release of circulating catecholamines is diminished, possibly reducing the associated arrhythmias. Morphine also causes peripheral venous and arterial vasodilatation, which reduces preload and afterload and, consequently, myocardial oxygen demand. However, retrospective studies have suggested the potential for increased mortality in patients with NSTE-ACS receiving morphine; thus, morphine carries a Class IIb recommendation in the 2014 ACC/AHA NSTE-ACS guidelines.[40] Clinicians should be aware of potential unwanted side effects of morphine such as hypotension, nausea, and respiratory depression.

The nonselective and cyclooxygenase (COX)-2–selective nonsteroidal antiinflammatory drugs (NSAIDs) have been associated with an increased risk of mortality, reinfarction, hypertension, HF, and myocardial rupture. These agents should be discontinued at the time a patient presents with ACS.[1,5]

Stool Softeners

It is common to administer agents such as docusate to prevent constipation in AMI patients because straining causes undesirable stress on the cardiovascular system.[1,5]

Oxygen

Many patients are modestly hypoxemic during the initial hours of an AMI. Supplemental oxygen should be administered to patients with ACS with an arterial saturation less than 90%, respiratory distress, or other high-risk features for hypoxemia. Patients with severe hypoxemia or pulmonary edema may require intubation and mechanical ventilation.[1,5]

Antiarrhythmic Agents

Ventricular arrhythmias, including ventricular fibrillation, are common complications associated with myocardial ischemia and AMI as well as a major cause of death. More than half of the episodes of ventricular fibrillation that occur with an AMI are within 1 hour of the onset of symptoms. If an antiarrhythmic agent is necessary, amiodarone is preferred over lidocaine (see Chapter 15, Cardiac Arrhythmias). The routine use of prophylactic lidocaine or other antiarrhythmic agents to prevent ventricular tachycardia and ventricular fibrillation is not recommended. Although lidocaine may reduce the number of episodes of ventricular fibrillation, it may contribute to an increased number of episodes of asystole.[5]

Suppression of ventricular ectopy after an AMI with the chronic use of oral antiarrhythmic agents is not recommended. Results of the Cardiac Arrhythmia Suppression Trial (CAST) showed an increase in mortality in asymptomatic patients with ventricular ectopy after an AMI who were treated with flecainide, encainide, or moricizine (see Chapter 15, Cardiac Arrhythmias).[41,42]

Nondrug Therapy

For STEMI, primary PCI is the preferred method for reperfusion as long as it can be performed in a timely fashion. Specific guidelines have been published by the ACC/AHA addressing PCI and stent use in AMI.[43]

For patients presenting to a PCI-capable hospital, PCI should be performed within 90 minutes after initial medical contact (also referred to as “door-to-balloon time”). If a patient is at a non-PCI facility, immediate transfer to primary PCI is preferred only if PCI can be performed within 120 minutes of first medical contact.[5] This threshold is based on a multivariant analysis of patients undergoing PCI in which an increased door-to-balloon time exceeding 120 minutes

---

was associated with a higher mortality rate.[44] Fibrinolytic therapy should be given to patients when the 120-minute time goal cannot be met, unless a contraindication is present.[5]

The disadvantages of PCI include the longer amount of time needed to mobilize the personnel needed to prepare the catheterization laboratory and its initial higher cost.

A potential advantage of PCI is the greater ability to achieve TIMI grade 3 flow in the affected vessel compared to fibrinolytic therapy (90% vs. 50%–60%, respectively).[5] PCI is associated with fewer major adverse cardiac events, irrespective of patient presentation time. Additionally, rates of major bleeding and intracranial hemorrhage are lower with PCI compared to fibrinolytic therapy. Unfortunately, many hospitals do not have the facilities or skilled personnel to complete this procedure in the necessary time frame.[5]

For NSTE-ACS, coronary angiography aids in defining the extent and location of coronary lesion and in directing the definitive care strategy (e.g., PCI with stent placement, CABG, or medical management). However, because angiography is an invasive procedure, there is a small risk of serious complications. Therefore, coronary angiography should be used only in patients for whom the procedure's benefits outweigh its risks. With this principle in mind, two pathways of treatment for NSTE-ACS patients have emerged: the early invasive strategy and the ischemia-guided strategy (Fig. 13-6). In the early invasive strategy, all patients without contraindications undergo coronary angiography with the intent to perform revascularization within 24 hours of hospital admission. The ischemia-guided strategy consists of aggressive medical therapy for all patients and coronary angiography only for those with certain risk factors or who fail medical therapy.

CLINICAL PRESENTATION OF ACS

CASE 13-1

QUESTION 1: P.H., a 68-year-old, 80-kg man, is being admitted to the ED after experiencing an episode of sustained chest pain while mowing his yard. After waiting 6 hours, he called 911 and was transported to the ED to a facility without the ability to conduct PCI. Physical examination reveals an anxious and diaphoretic man. Heart rate and rhythm are regular, and no S_3 or S_4 sounds are present. Vital signs include BP 180/110 mm Hg, heart rate 105 beats/minute, and respiratory rate 32 breaths/minute. P.H.'s chest pain radiates to his left arm and jaw, and he describes the pain as "crushing" and "like an elephant sitting on my chest." He rates it as a "10/10" in intensity. Thus far, his pain has not responded to five SL NTG tablets at home and three more in the ambulance. His ECG reveals a 3-mm ST segment elevation and Q waves in leads I and V_2 to V_4. Based on his history and physical examination, P.H. is diagnosed with an anterior infarction. Laboratory values include the following:

Sodium (Na), 141 mEq/L
Potassium (K), 3.9 mEq/L
Chloride (Cl), 100 mEq/L
CO_2, 20 mEq/L
Blood urea nitrogen (BUN), 19 mg/dL
Serum creatinine (SCr), 1.2 mg/dL
Glucose, 149 mg/dL
Magnesium (Mg), 2 mEq/L
CK, 1,200 U/L, with a 12% CK-MB fraction (normal, 0%–5%)
Troponin I-Ultra, 60 ng/mL (normal, <0.02 ng/mL)
Cholesterol, 259 mg/dL

Triglycerides, 300 mg/dL

P.H. has a prior history of CAD. A previous cardiac catheterization 2 years ago revealed lesions in his middle left anterior descending coronary artery (75% stenosis) and proximal left circumflex artery (30% stenosis). His echocardiogram at the time showed an EF of 58%. These lesions were deemed suitable for medical management. He also has a history of recurrent bouts of bronchitis associated with bronchospasm for 10 years, diabetes mellitus treated with insulin for 18 years with a hemoglobin A_{1c} of 6.8% obtained 6 months prior to admission, and hypertension with BPs usually 140/85 mm Hg. His father died of an MI at age 70. His mother and siblings are all alive and well. P.H. has smoked one pack of cigarettes a day for 30 years, and he drinks approximately one six-pack of beer a week. He has no history of IV drug use. On admission, P.H.'s medications include insulin glargine 40 units daily; albuterol inhaler as needed (PRN) for shortness of breath; hydrochlorothiazide 25 mg daily; NTG patch 0.2 mg/hour; and NTG SL 0.4 mg PRN for chest pain.

What signs and symptoms does P.H. have that are consistent with the diagnosis of AMI?

P.H. described his pain as a pressure sensation, which is common with ischemic heart disease. The chest discomfort associated with ACS often is described as pressure or as a tight band around the chest rather than pain. Although P.H. was involved in physical exertion when his chest discomfort began, this is not always the case. It can begin at rest and, frequently, in the early morning hours. At least 20% of patients with AMI have no pain or discomfort; these episodes are described as "silent" MIs.[5] Presentations range from no symptoms to shortness of breath, hypotension, HF, syncope, or ventricular arrhythmias. Silent or atypical infarctions occur more commonly in people with diabetes and in the elderly. P.H. is diaphoretic, a common finding, but other common symptoms such as nausea and anxiety are not present. He also describes his pain as "10/10" in intensity, or perhaps "the worst pain I've ever experienced," which is typical of a STEMI. The diagnosis primarily lies in the symptoms (e.g., the patient's "story"), the ECG, and the laboratory findings.

The history of diabetes, hypertension, smoking, and a positive family history in P.H. are all risk factors for coronary disease. His admission BP is high, which could indicate poor underlying control or anxiety and stress related to his ACS. The blood sugar of 149 mg/dL is high, again indicating either poor control or a stress response. Measurement of glycosylated hemoglobin is indicated during his hospitalization to better assess his diabetes control.

Laboratory Abnormalities

CASE 13-1, QUESTION 2: What laboratory abnormalities can you expect to see in P.H.?

P.H. demonstrates several laboratory abnormalities commonly seen with both STEMI and NSTEMI. Both his CK-MB and troponin are elevated, consistent with myocardial necrosis. With UA, cardiac biomarkers are not elevated. Several other nonspecific laboratory findings should be monitored in P.H. Hyperglycemia may develop because P.H. has diabetes, but this can also occur in patients without diabetes. ACS is also accompanied by an acute systemic inflammatory response manifested by fever, leukocytosis, and elevation of the erythrocyte sedimentation rate and C-reactive protein, as well as a drop in LDL, high-density lipoprotein, and total cholesterol. Specifically, these lipoprotein changes may begin to decrease within 24 to 48 hours after an ACS event, reaching a nadir within 5 to 7 days and then gradually recovering during the next 30 days.[45] Therefore, it is prudent to check serum lipid profiles within the first 24 hours of the AMI to get an accurate determination of the patient's lipid values.

ST Segment Elevation Myocardial Infarction Versus Non–ST Segment Elevation Myocardial Infarction

CASE 13-1, QUESTION 3: P.H. was noted to have ST segment elevation on the ECG. What are the implications of an ST segment elevation versus non–ST segment elevation MI?

Perhaps the most important diagnostic test in someone suspected of having an AMI is the ECG. The ECG is an important tool because it is noninvasive, can be performed rapidly, is readily available in most settings, and helps determine where the AMI is located (i.e., anterior, inferior, lateral). P.H. has classic ECG changes (ST segment elevation), and presence in the anterior ECG leads (V_2–V_4) points to the coronary artery likely to be blocked. P.H.'s previous left anterior descending lesion may have had a plaque rupture leading to thrombosis of the vessel.

The presence of ST segment elevation in two contiguous leads indicates severe ischemia and occlusion of the coronary artery. Every effort should be made to open the infarct-related artery as soon as possible, which could consist of PCI or fibrinolytic therapy. If the ECG showed ST segment depression (e.g., NSTE-ACS), instead of elevation, P.H. would not be eligible for fibrinolytic therapy because the risks of fibrinolytic therapy outweigh the benefits in NSTE-ACS.

Anterior Versus Inferior Infarction

CASE 13-1, QUESTION 4: What are the prognostic implications of an anterior versus an inferior MI?

Damage to the anterior section of the heart is more likely to be associated with increased morbidity (e.g., LV dysfunction) and mortality. The patients at highest risk of death are those with an anterior ACS, LV dysfunction, and complex ventricular ectopy. P.H. is at an increased risk because he has sustained an anterior infarction.

Risk Stratification

CASE 13-1, QUESTION 5: What is P.H.'s initial risk of mortality based on his presenting signs and symptoms?

Using the TIMI Risk Score for STEMI, P.H. has a score of 6 based on his age (2 points); history of angina, hypertension, and diabetes (1 point); heart rate (2 points); and location of his MI (1 point) (Table 13-1). P.H. has a 30-day mortality rate of 16%, thereby highlighting the serious nature of this event. If P.H. had experienced an NSTE-ACS with ST segment depression, he would have a TIMI risk score of 5 based on his age (1 point); at least three risk factors for CAD (1 point), prior CAD history (1 point), ST segment deviation (1 point), and elevated cardiac biomarkers (1 point). Based on this TIMI risk score, P.H. would be at high risk for death, MI, or need for urgent coronary artery revascularization within 30 days.

Therapeutic Objectives

CASE 13-1, QUESTION 6: What are the immediate and long-term therapeutic objectives in treating P.H.?

With both STEMI and NSTE-ACS, the immediate therapeutic objectives particularly as they apply to P.H. are to restore blood flow to the infarct-related artery, arrest infarct expansion, alleviate his symptoms, and prevent death. These objectives are achieved primarily by restoring coronary blood flow (administering a fibrinolytic or performing PCI for STEMI or performing PCI with NSTE-ACS) and lowering myocardial oxygen demand with nitrates and β-blockers. Any life-threatening ventricular arrhythmias that develop must be treated. The long-term therapeutic objectives are to prevent or minimize recurrent ischemic symptoms, reinfarction, HF, and sudden cardiac death. As P.H. is experiencing a STEMI, the specific therapeutic regimens are discussed in the questions that follow.

TREATMENT FOR ST SEGMENT ELEVATION MYOCARDIAL INFARCTION

Fibrinolytic Therapy

CASE 13-1, QUESTION 7: Is P.H. a candidate for fibrinolytic therapy? Is any one agent preferred?

STEMI is a medical emergency, and rapid administration of drug therapy is crucial to save myocardial tissue. The results of several major trials have shown unequivocally that if used appropriately, fibrinolytic agents can reduce the mortality associated with an AMI. Because mortality benefit is greatest when fibrinolytic therapy is administered within 2 hours of symptom onset, prehospital fibrinolytic therapy, in which trained paramedics administer the fibrinolytic in the field, is an attractive option to reduce total ischemic time.[46] If primary PCI cannot be performed within 120 minutes, fibrinolytic therapy should be given if no contraindications are present. For patients who present >12 hours after symptom onset, fibrinolytic therapy should be administered only if there is ongoing ischemia, hemodynamic instability or a large area of myocardium is involved. In the case of P.H., he is admitted to a hospital that is not PCI capable and cannot be transferred to a PCI-capable hospital within 120 minutes of first medical contact.

Controversy still exists about which fibrinolytic should be used, the best dosing regimen, the most appropriate adjunctive therapy, and whether the risk outweighs the benefit in some subpopulations of patients (e.g., those with an inferior AMI). P.H. has a history of hypertension, and at presentation his BP is 180/110 mm Hg. A BP this high is a relative contraindication to fibrinolytic therapy because of an increased risk of cerebral hemorrhage; however, P.H. has an anterior MI and is likely to benefit from fibrinolytic therapy. In this case, he should receive IV NTG immediately because the onset of BP control with this agent usually occurs within minutes. Once his systolic BP is less than 180 mm Hg and the diastolic is less than 110 mm Hg, a fibrinolytic can be administered. The NTG will also reduce the workload on his heart and may provide pain relief.

Because P.H. has severe pain and ECG changes consistent with an anterior AMI, he is at high risk for substantial morbidity or mortality. The argument for or against a specific fibrinolytic is probably less important than the decision to use an agent and to administer the medication as soon as possible after the onset of symptoms. P.H. is fortunate because he has presented within 1 hour of the onset of chest pain. Options in the United States include only fibrin-specific agents (Table 13-3).

Reteplase was compared with t-PA in the Global Utilization of Streptokinase and t-PA for Occluded Arteries (GUSTO)-III trial.[47] Reteplase has a slower clearance from the body, allowing the drug to be given as a bolus without the need for a constant infusion. In the GUSTO-III trial, reteplase was administered in two bolus doses of 10 million units, given 30 minutes apart. The mortality

---

rate and incidence of stroke were the same in the two groups of patients. Tenecteplase (TNK) was compared with t-PA in the Second Assessment of Safety and Efficacy of a New Fibrinolytic (ASSENT-2) trial.[48] Tenecteplase was administered as a bolus of 30 to 50 mg for 5 to 10 seconds, based on body weight. No difference existed between TNK and t-PA in 30-day mortality and stroke and TNK had fewer bleeding complications. The 2013 guidelines do not explicitly endorse one fibrinolytic versus another, and all are acceptable first-line agents. Selection is usually based on clinician preference and hospital formulary.

ADJUNCT THERAPY

CASE 13-1, QUESTION 8: Orders are written for an infusion of t-PA along with UFH 4,000 units IV bolus, followed by 960 units/hour by continuous infusion. Aspirin 325 mg is ordered stat. Are both UFH and aspirin agents necessary?

The Second International Study of Infarct Survival (ISIS)-2 trial showed that the combination of aspirin and streptokinase reduced mortality in patients with an AMI by 42% compared to placebo.[49] In doses of 162 mg or more, aspirin generates a prompt clinical antithrombotic effect as a result of its inhibition of thromboxane A_2 production. Thus, immediate administration of 162 to 325 mg of aspirin in all patients diagnosed with ACS is indicated. In the acute setting, aspirin should be chewed because it is absorbed more quickly. All patients should receive low-dose aspirin indefinitely after a diagnosis of ACS. If patients have a contraindication to aspirin, clopidogrel can be substituted.[5]

The use of UFH as adjunct therapy to prevent reocclusion has been evaluated in many studies.[5] Because P.H. will receive t-PA, an IV UFH bolus followed by a continuous infusion should be started before the end of the t-PA infusion. The ACC/AHA guidelines recommend an initial UFH bolus of 60 units/kg (maximum of 4,000 units), followed by an initial infusion of 12 units/kg/hour (maximum of 1,000 units/hour) for 48 hours after fibrinolysis, with a targeted activated partial thromboplastin time (aPTT) of 1.5 to 2 times the upper limit of normal. UFH should always be considered in patients at high risk for systemic or venous embolism.

CASE 13-1, QUESTION 9: Would P.H. benefit from the addition of clopidogrel to his current drug regimen?

Two studies have evaluated the potential role of in-hospital clopidogrel as an integral part of fibrinolytic therapy in patients with STEMI.[50,51] The Clopidogrel as Adjunctive Reperfusion Therapy–Thrombolysis in Myocardial Infarction 28 (CLARITY-TIMI 28) evaluated patients with STEMI who received standard fibrinolytic therapy, aspirin, and UFH, and were scheduled for angiography within 2 days.[51] Patients received either clopidogrel (300 mg loading dose, followed by 75 mg daily) or placebo within 10 minutes of fibrinolytic administration. Clopidogrel was continued up to and including the day of angiography and then stopped. The primary end point was the composite of an occluded infarct-related artery on predischarge angiography or death or an MI up to the start of coronary angiography. Compared with placebo, patients receiving clopidogrel demonstrated a 36% reduction in the primary end point ($p < 0.001$). By 30 days, the clopidogrel treatment group had a 20% reduction in cardiovascular death, recurrent MI, or recurrent ischemia ($p = 0.03$). No difference in the rate of major bleeding was seen between groups. In a substudy of patients proceeding to nonemergent PCI after fibrinolytic therapy, patients receiving pretreatment with clopidogrel demonstrated a 66% reduction in 30-day mortality compared with those receiving placebo ($p = 0.034$).[52]

The Clopidogrel and Metoprolol in Myocardial Infarction Trial (COMMIT) evaluated the effect of clopidogrel 75 mg daily (with no loading dose) or placebo in 45,852 patients presenting with STEMI.[50] In the trial population, 93% had ST segment elevation or bundle branch block, 7% had ST segment depression, and 54% were treated with fibrinolytic therapy. The initial clopidogrel dose was given within 24 hours of symptom onset and continued until hospital discharge or up to 4 weeks in the hospital. Compared with placebo, clopidogrel was associated with a 9% reduction in death, reinfarction, or stroke ($p = 0.002$), and a 7% reduction in all-cause mortality ($p = 0.03$). No significant excess in bleeding was noted with clopidogrel, either overall or in patients who received concomitant fibrinolytic therapy or were older than 70 years. On the basis of these two studies, P.H. should receive clopidogrel as an inpatient.

CASE 13-1, QUESTION 10: What dose of clopidogrel should be considered?

According to the 2013 ACC/AHA guidelines, clopidogrel should be added to aspirin in patients who undergo reperfusion with fibrinolytic therapy.[5] A loading dose of clopidogrel 300 mg can be administered with fibrinolytic therapy followed by 75 mg/day for maintenance. The maintenance dose should be continued for 14 days and up to 1 year. The 1-year duration is extrapolated from experience with NSTE-ACS.[1] There are no studies evaluating a 600-mg loading dose in patients with STEMI treated with fibrinolytics. Additionally, uncertainty exists about the safety of giving a loading dose of clopidogrel in adults 75 years of age and older, particularly when they receive a fibrinolytic. Therefore, in this population, a loading dose should be avoided. A single loading dose of 300 mg of clopidogrel should be given to patients less than 75 years of age who receive a fibrinolytic agent and are subsequently proceeding to PCI within 24 hours.[5] If the patient received a fibrinolytic and then proceeds to PCI after 24 hours has lapsed, then a loading dose of 600 mg is preferred. For P.H., a loading dose of 300 mg of clopidogrel should be administered at the time of fibrinolytic administration followed by 75 mg/day for 14 days to 1 year. Because P.H. has already received 325 mg of aspirin in the ED, he should continue 81 mg of daily aspirin indefinitely.

CASE 13-1, QUESTION 11: What roles do the other anticoagulant and antiplatelet agents have in P.H.'s management?

Data available with the newer $P2Y_{12}$ inhibitors when used in the setting of fibrinolytic therapy are lacking. It would be prudent to avoid giving prasugrel and other potent $P2Y_{12}$ antagonists no sooner than 24 hours after administration of a fibrinolytic.[5] Coronary anatomy should be known to ensure the patient is not a candidate for CABG.

The replacement of UFH with a LMWH, factor Xa inhibitor, or the addition of a GP IIb/IIIa inhibitor to fibrinolytic therapy has been evaluated in patients with

STEMI.

In the Enoxaparin and Thrombolysis Reperfusion for Acute Myocardial Infarction Study-25 (ExTRACT-TIMI 25), 20,506 patients with STEMI scheduled for fibrinolytic therapy were randomized to receive either enoxaparin or continuous infusion of UFH for 48 hours.[53] Enoxaparin was dosed according to age and renal function. UFH was dosed according to weight and adjusted to achieve an aPTT 1.5 to 2.0 times control. The composite end point of death or nonfatal MI through 30 days occurred in 12.0% in the UFH group and 9.9% in the enoxaparin group, representing a 17% risk reduction ($p < 0.001$). No difference was noted in mortality between the two groups. Major bleeding was higher in the enoxaparin group.

The Organization for the Assessment of Strategies for Ischemic Syndromes (OASIS) 6 was a randomized double-blind trial of 12,092 patients with STEMI assessing the effect of early initiation of fondaparinux with primary PCI and medical therapy.[54] The study compared the effects of fondaparinux with two different control arms. Patients with confirmed STEMI were assigned into one of the two following strata. Stratum 1: no indication for UFH (patients receiving streptokinase or those not receiving a thrombolytic agent) were assigned to this stratum. Stratum 2: indication for UFH (patients receiving alteplase, reteplase, or tenecteplase, and those undergoing primary PCI) were assigned to this stratum. Death or reinfarction at 30 days was significantly reduced in the fondaparinux group. However, fondaparinux did not benefit patients who were managed with primary PCI. Although the rates of death, MI, and severe bleeds did not differ in these patients, there was a higher rate of catheter thrombosis with fondaparinux.[54]

The TIMI-14 trial demonstrated enhanced reperfusion (TIMI 3 flow) using reduced-dose t-PA combined with abciximab compared with full-dose t-PA alone. [55] The GUSTO-V trial compared standard-dose reteplase to half-dose reteplase plus full-dose abciximab in STEMI patients.[56] The combination group had less reinfarction and recurrent ischemia, but more episodes of moderate and severe bleeding, especially in the elderly. Similar rates of enhanced reperfusion have also been observed with the combination of double-bolus dose eptifibatide (180/90 mcg/kg, 10 minutes apart) with a 48-hour infusion (2 mcg/kg/minute) plus half-dose t-PA (50 mg). [57] The ASSENT-3 trial assessed three regimens: (1) full-dose TNK plus enoxaparin or (2) full-dose TNK plus UFH or (3) half-dose TNK plus UFH with a 12-hour infusion of abciximab. The addition of either abciximab or enoxaparin to TNK reduced the composite end point of 30-day mortality, in-hospital reinfarction, or ischemia compared with UFH. More major bleeding complications were seen with abciximab compared with UFH.[58] In a meta-analysis of 11 trials involving 27,115 STEMI patients who received adjunctive abciximab in addition to either PCI or fibrinolytic therapy, use of abciximab was associated with a significant reduction in 30-day ($p = 0.047$) and 1- to 6-month mortality ($p = 0.01$) in patients undergoing PCI but not in those receiving fibrinolytic therapy.[59] Despite an improvement in patency rates, the combination of GP IIb/IIIa inhibitors with either full- or half-dose fibrinolytic should be avoided if at all possible, especially in the elderly.[5]

Based on data from ExTRACT-TIMI 25 and OASIS-6, the ACC/AHA guidelines allow for substitution of UFH with either enoxaparin or fondaparinux.[5] However, whereas fondaparinux appeared to be superior to control therapy in the OASIS-6 trial, relative benefit compared with placebo and UFH separately cannot be reliably determined.[60] If enoxaparin or fondaparinux are selected, anticoagulation should be continued for the duration of the hospitalization, up to 8 days or until revascularization. For P.H., enoxaparin would be the more appropriate choice; however, he will have a higher risk for bleeding and need to be monitored closely. Because P.H. is not undergoing PCI, the bleeding risks outweigh any benefit from the addition of a GP IIb/IIIa at this time.[5]

DETERMINATION OF REPERFUSION

CASE 13-1, QUESTION 12: How can you monitor for successful reperfusion in P.H. after he has received fibrinolytic therapy?

It is important to determine whether thrombolysis has been successful because the prognosis of the patient is related to the presence or absence of an open infarct-related artery. If fibrinolytic therapy fails to open the infarct-related artery, then the patient may benefit from PCI or a CABG. Although coronary angiography has been the standard for determining the success of reperfusion, this procedure is expensive and may be misleading, as some studies have suggested that microvascular perfusion may be impaired even when TIMI grade 3 flow has been achieved. A simple and readily available technique is evaluation of ECG ST segment resolution. A resolution of more than 50% of the ST segment elevation at 60 to 90 minutes after the initiation of fibrinolytic therapy is a good indicator of improved myocardial perfusion.[5] Relief of symptoms, maintenance or restoration of hemodynamic or electrical stability or both, and a reduction of >70% in the initial ST segment elevation are all suggestive of adequate reperfusion. P.H. should undergo a 12-lead ECG to evaluate reperfusion.[5]

CASE 13-1, QUESTION 13: P.H. continues to have chest pain, should the thrombolytic be readministered?

READMINISTRATION OF THROMBOLYTIC AGENTS

Reocclusion of the infarct-related artery after initial successful thrombolysis is a major setback. If reocclusion occurs, mechanical intervention (e.g., PCI) is often attempted. Several studies have evaluated whether to readminister the fibrinolytic or refer the patient for PCI. In a meta-analysis of eight trials of patients with STEMI who failed fibrinolytic therapy, those receiving rescue PCI showed no significant reduction in all-cause mortality, but had a 27% risk reduction in HF ($p = 0.05$) and 42% reduction in reinfarction ($p = 0.04$) when compared with standard medical therapy. Repeat fibrinolytic therapy was not associated with significant improvements in all-cause mortality or reinfarction. Both treatment strategies demonstrated a significant increase in minor bleeding, but PCI was associated with an increase in stroke.[61] The Rapid Early Action for Coronary Treatment (REACT) study found that patients who received rescue PCI compared to repeat fibrinolytic or conservative care had a significantly lower composite of death, reinfarction, stroke, or severe HF at 6 months (event-free survival rate: 84.6% vs. 70.1% vs. 68.7%, respectively, $p = 0.004$).[62] The ACC/AHA guidelines recommend that patients who have failed fibrinolytic therapy undergo catheterization with appropriate antithrombotic therapy if possible.[5] Patients best suited for catheterization consist of those with high-risk features such as cardiogenic shock, significant hypotension, severe HF, or ECG evidence of an extensive area of myocardial jeopardy.

In the case of P.H., a repeat infusion with t-PA would probably be safe, but it may not be effective. If a PCI-capable institution exists, P.H. should be transferred for an invasive strategy at this time.

USE IN THE ELDERLY

CASE 13-1, QUESTION 14: If P.H. had been 85 years of age, should he have still received fibrinolytic therapy?

Some of the early trials with fibrinolytic therapy excluded the elderly. Although the elderly may have a higher prevalence of relative contraindications such as severe hypertension or history of stroke at presentation, they also have a higher incidence of mortality after an AMI. The 30-day mortality rate after an AMI is 19.6% for patients between 75 and 84 years of age and 30.3% for those who are 85 years of age and older.[63] In the ISIS-2 trial, the greatest reduction in mortality occurred in the elderly subgroup. There are no controlled trials in which fibrinolytic therapy has increased mortality in the elderly. However, in a high-risk cohort of elderly female patients (older than 75 years, <67 kg), the ASSENT investigators demonstrated that TNK was associated

---

with lower rates of major bleeding and intracerebral hemorrhage compared to t-PA. Another potential strategy to reduce intracranial hemorrhage risk is a reduced dose of fibrinolytic. The Strategic Reperfusion Early after Myocardial Infarction (STREAM) trial evaluated prehospital fibrinolytic therapy and reduced the dose of TNK by 50% in patients ≥75 years of age.[63] The intracranial hemorrhage rate was reduced to 0.5% and coronary patency rates were similar when compared to patients <75 years of age who received full-dose TNK. It is also important to ensure appropriate dosage adjustments are made for concomitant medications according to age (e.g., enoxaparin), weight (e.g., prasugrel), and renal function (e.g., enoxaparin and fondaparinux).

β-Blockers

CASE 13-1, QUESTION 15: The physician wishes to write a prescription for a β-blocker. What are the benefits of administering a β-blocker to P.H.? Should it be given as IV therapy or started as oral therapy a few days after the infarction?

β-Blockers offer significant benefits to the MI patient. Several large trials gave IV β-blockers (up to 24 hours after symptom onset) followed by oral therapy; other studies used oral therapy alone beginning days after the infarction. Early IV administration appears to be most beneficial, with a reduction in mortality of about 25% in the first 2 days when the results of these trials are pooled. However, late oral therapy alone, initiated up to 21 days after an MI in the β-Blocker in Heart Attack Trial, was also associated with a substantial reduction in mortality (around 10%).[5]

Early IV administration of propranolol, metoprolol, timolol, and atenolol has been studied. Typically, metoprolol is used in the acute setting because of its β_1 selectivity, ease of dosing and administration, and weight of evidence. Oral carvedilol, a nonselective β- and α-blocker, has been used in the peri-infarction period, specifically in patients with LV dysfunction. In the Carvedilol Post-Infarction Survival Control in Left Ventricular Dysfunction (CAPRICORN) trial, carvedilol 6.25 mg twice daily titrated to 25 mg twice daily reduced all-cause and cardiovascular mortality as well as recurrent nonfatal MI.[64]

It is important to tailor β-blockade therapy for each patient, as evidenced in the COMMIT trial.[65] In this study, patients were randomized to placebo or metoprolol (up to 15 mg IV of metoprolol, then oral 200 mg metoprolol succinate daily) within 24 hours of AMI. Although metoprolol reduced reinfarction and ventricular fibrillation rates compared with placebo, it was associated with a significant increase in cardiogenic shock. Patients with hemodynamic instability at randomization were at greatest risk of early cardiogenic shock associated with metoprolol. Given these concerns, oral β-blockers are generally preferred. If the patient is hypertensive or having ongoing ischemia, then IV metoprolol tartrate (5 mg IV every 5 minutes as tolerated up to three doses) can be considered (see Table 13-2). For all other patients without contraindications, oral metoprolol tartrate 25 to 50 mg every 6 to 12 hours should be initiated. Doses should be titrated on the basis of BP and heart rate. If a patient has transient cardiac decompensation or is at risk for cardiogenic shock during the acute infarction period, early IV β-blockers should be withheld. The patient's condition may be observed for a few days; if it stabilizes, oral therapy is initiated and titrated slowly. The ACC/AHA guidelines highlight the importance of an individualized approach, but do provide guidance on suggested dosing recommendations for both acute and long-term use.

In our case, P.H.'s situation is complicated by his history of intermittent pulmonary problems. In deciding whether to attempt use of β-blockers in patients with pulmonary disease, one must determine the nature of the pulmonary problem (i.e., reactive airway disease). It also would be helpful to determine P.H.'s need for routine use of β-agonists to help quantify the severity of his disease. By history, P.H. does not use β-agonist bronchodilators routinely. No history is given regarding his pulmonary function tests or the degree of reversibility of his airway disease with bronchodilators. β_1-selective antagonists are the drugs of choice in these patients, but at higher doses (e.g., metoprolol doses > 100 mg/day), the relative β_1-selectivity may be lost. A patient would need to experience significant worsening of the pulmonary disease to justify avoiding β-blockers. A better history of P.H.'s pulmonary problems should be obtained. If they are minor and as he has experienced an uncomplicated MI, P.H. may be a candidate for early therapy with metoprolol to reduce chest pain as well as decrease the risk of reinfarction and arrhythmias.

Nitroglycerin

CASE 13-1, QUESTION 16: Despite SL NTG, P.H. continues to have chest discomfort. Would he benefit from IV NTG?

Because P.H. is exhibiting refractory ischemic discomfort despite receiving SL and topical nitrates, symptomatic management with IV NTG is indicated. NTG lowers the LV filling pressure and systemic vascular resistance, thereby reducing myocardial oxygen consumption and myocardial ischemia. At lower doses (<50 mcg/minute), IV NTG preferentially dilates the venous capacitance vessels, which leads to a decrease in LV filling pressure. For patients who have signs of pulmonary congestion, IV NTG is of particular value.

CASE 13-1, QUESTION 17: How should IV NTG be administered to P.H.? How should it be monitored?

A continuous infusion of NTG is delivered in a controlled manner, starting with 5 to 10 mcg/minute, which is then increased by an additional 5 to 10 mcg/minute every 5 to 10 minutes if needed. Many cardiologists routinely give patients an infusion of NTG for the first 24 to 48 hours after an AMI. Increasing doses may be required during this period to maintain the desired hemodynamic effect owing to tolerance that occurs from prolonged nitrate exposure. However, if more than 200 mcg/minute is needed to achieve the desired response, another vasodilator may be needed. NTG is typically administered in combination with fibrinolytic agents in patients who require relief from myocardial ischemia.

Patients with an inferior or right ventricular infarct often develop hypotension (mean BP < 80 mm Hg) when given NTG. P.H.'s BP should be monitored closely during this infusion. After starting NTG, we would expect to see his BP decline; the pulse rate may or may not increase. The NTG dose should be titrated to relieve pain while avoiding symptomatic hypotension. In patients with evidence of HF, NTG can reduce LV filling pressure (preload), as well as improve orthopnea and pulmonary congestion. However, excessive doses of IV NTG can reduce LV filling pressure to excess, and potentially decrease cardiac output. The systolic BP should be maintained to at least 90 mm Hg. Once P.H.'s chest pain is controlled, he may be transitioned to either an oral agent or his transdermal delivery system increased. With either choice, a nitrate-free interval should be maintained (see Chapter 12, Chronic Stable Angina).

TREATMENT FOR UNSTABLE ANGINA OR NON–ST SEGMENT ELEVATION MYOCARDIAL INFARCTION

Invasive Versus Ischemia-Guided Strategy

CASE 13-2

QUESTION 1: J.W. is a 65-year-old man who presents to the ED with chest tightness and shortness of breath. He gives a history of similar symptoms the previous day that lasted 20 minutes. He was given aspirin 325 mg, intranasal oxygen, PO metoprolol tartrate, and started on an IV NTG infusion, which was increased to 80 mcg/minute; at that time, his BP was 130/60 mm Hg, and his heart rate was 88. His ECG revealed ST segment depression in the anterior leads. His shortness of breath was relieved, but he still complained of chest tightness. His past medical history includes hypertension for which he takes hydrochlorothiazide 25 mg daily. His mother died of a heart attack at age 62. He has smoked a pack of cigarettes per day for the past 30 years. Laboratory values include the following:

Na, 135 mEq/L
K, 4.0 mEq/L
Cl, 100 mEq/L
CO_2, 20 mEq/L
BUN, 15 mg/dL
SCr, 1.1 mg/dL
Glucose, 100 mg/dL
Mg, 2 mEq/L
CK-MB fraction, 1% (normal, 0%–5%)
Troponin I-Ultra, 0.05 ng/mL (normal, <0.02 ng/mL)
Hgb, 14 g/dL
Hct, 44%
Plt, $288 \times 10^3/\text{mm}^3$

Based on his symptoms and ECG, the diagnosis is presumed UA. Should J.W. receive an invasive or ischemia-guided strategy for management of his NSTE-ACS?

Although J.W. has negative biomarkers after 24 hours from his first episode of chest pain suggesting UA, the presence of new ST segment depression may prompt the clinician to choose an early invasive approach within 24 hours (see Fig. 13-6). If however, the patient is not at high or intermediate risk, then the invasive approach may be delayed and performed within 25 to 72 hours. A TIMI score would also be helpful to risk stratify the patient. J.W. has a score of 4 indicating a 19.9% risk at 14 days of all-cause mortality, new or recurrent MI, or severe recurrent ischemia requiring urgent revascularization. When risk stratifying, scores of 0 to 2, 3 to 4, and 5 to 7 represent low, moderate, and high risk for death or repeat MI at 14 days. So, based on his TIMI risk score, he is moderate risk. As an alternative, calculating a GRACE score would indicate 137 points representing an 11% risk of in-hospital death or MI and a 19% risk at 6 months. An ischemia-guided strategy might be selected based on patient or clinician preference in the absence of high-risk features such as elevated biomarkers. In this approach, pharmacotherapy would be initiated followed by a noninvasive stress evaluation. If J.W. were to have elevated cardiac biomarkers during his presentation, his diagnosis would be NSTEMI and an early invasive (within 24 hours) approach may be preferred. If during his hospitalization, J.W. were to experience any recurrent ischemia, arrhythmias, or signs and symptoms of HF, he would proceed directly to angiography and undergo possible PCI.

Anticoagulant Therapy

CASE 13-2, QUESTION 2: What anticoagulant regimen should J.W. receive?

The ACC/AHA guidelines recommend beginning anticoagulant therapy for all patients (without contraindications) with NSTE-ACS as soon as possible. The guidelines recommend one of four agents: UFH, enoxaparin, fondaparinux, or bivalirudin (approved only for patients managed according to an invasive strategy). Table 13-2 summarizes the dosing and contraindications for each of these agents.

In NSTE-ACS, UFH has been associated with lower rates of death or MI than aspirin alone.[1] Despite its limitations, UFH is preferred if the patient is to undergo CABG because of its rapid clearance. For an invasive strategy, the guidelines give a higher level of evidence for enoxaparin but do warn about an increase in bleeding.[1] When choosing an anticoagulant, renal function, bleeding risk, and concomitant therapy should be considered.

Data supporting LMWHs in this setting come from several studies. In the Efficacy and Safety of Subcutaneous Enoxaparin (ESSENCE) study, enoxaparin (1 mg/kg SQ twice daily) was compared with UFH (5,000 units IV bolus followed by continued infusion titrated to an aPTT of 55 to 86 seconds).[66] The composite outcome of death, MI, or recurrent angina at 14 days was reduced by 20% in the enoxaparin group. This benefit was maintained for 1 year.

In the Superior Yield of the New Strategy of Enoxaparin, Revascularization and Glycoprotein IIb/IIIa Inhibitors (SYNERGY) trial, 9,978 high-risk NSTE-ACS patients were randomized to enoxaparin (1 mg/kg SQ twice daily) or weight-based UFH (60 units/kg bolus followed by 12 units/kg/hour adjusted to an aPTT 1.5 to 2 times control) before undergoing an early invasive strategy.[67] Enoxaparin was found to be as efficacious as UFH in reducing 30-day all-cause mortality or nonfatal MI but was associated with a significant risk of major bleeding ($p = 0.008$). Bleeding was especially problematic in those patients who crossed over from one treatment to the other during the trial.

In the TIMI-11B trial, enoxaparin (30 mg IV bolus followed by 1 mg/kg SQ twice daily for 8 days) compared with UFH (70 units/kg bolus followed by 15 units/kg/hour for 3 to 8 days) reduced the composite end point of death, MI, or need for urgent revascularization.[68] The benefit of enoxaparin is greatest for high-risk subgroups such as those with ST segment changes, elevated troponins, and a high TIMI risk score.[1]

Finally, enoxaparin has been compared with fondaparinux. In the OASIS-5 trial, NSTE-ACS patients were randomized to fondaparinux (2.5 mg SQ daily) or enoxaparin (1 mg/kg SQ twice daily) for a mean of 6 days and evaluated at 9 days for the primary end point of death, MI, or refractory ischemia.[69] There was no difference between groups for the primary end point; however, compared with enoxaparin, fondaparinux had a significantly lower incidence of major bleeding at 9 days ($p < 0.001$) and a greater reduction in mortality at 30 days ($p = 0.05$). Based on these data, the guidelines give preference to fondaparinux compared with other anticoagulants for patients who are at an increased risk of bleeding and being treated with an ischemia-guided (conservative medical management) strategy. If fondaparinux is used for a patient undergoing PCI, an additional anticoagulant with factor IIa activity such as UFH is needed.[1]

Bivalirudin is given a Class I recommendation in the guidelines. In the Acute Catheterization and Urgent Intervention Triage Strategy (ACUITY) trial, patients with NSTE-ACS managed with an early invasive strategy were randomly assigned to receive either UFH (or enoxaparin) plus a GP IIb/IIIa inhibitor, bivalirudin plus a GP IIb/IIIa inhibitor, or bivalirudin alone.[70] No differences in the primary end point (composite of death, MI, unplanned revascularization for ischemia, and major bleeding at 30 days) were observed between the group receiving UFH plus a GP IIb/IIIa inhibitor and the group receiving bivalirudin plus a GP IIb/IIIa inhibitor. However, compared with those receiving UFH plus a GP IIb/IIIa inhibitor, the 30-day composite of ischemia or major bleeding was significantly lower for those receiving bivalirudin alone. This difference was attributed to reduced major bleeding with bivalirudin.

The Unfractionated Heparin versus Bivalirudin In Primary Percutaneous Coronary Intervention (HEAT-PPCI) trial was a head to head comparison of bivalirudin versus UFH.[71] Patients who underwent emergent PCI were randomly assigned to receive either UFH or bivalirudin. At 28 days, the primary efficacy outcome of ≥1 major adverse cardiac events was significantly lower in the UFH group. When the individual components were evaluated, there was no difference in all-cause mortality or cerebrovascular accident. The driving factors favoring heparin were new MI or reinfarction and additional unplanned target lesion revascularization. The majority of these cases were related to stent thrombosis in the bivalirudin group (0.9% vs. 3.4%, $p = 0.001$). Major and minor bleeding events did not differ between the two groups.

Because J.W. is receiving an invasive strategy for his NSTE-ACS and he has adequate renal function, enoxaparin, UFH, or bivalirudin could be initiated and continued until the end of PCI.

Antithrombotic Therapy

CASE 13-2, QUESTION 3: What oral antithrombotic medications should be considered for J.W.?

For both an ischemia-guided and invasive strategy, aspirin along with a $P2Y_{12}$ antagonist (loading with maintenance dose) should be added as soon as possible to anticoagulant therapy unless the patient is to proceed to CABG. For an invasive strategy, prasugrel or ticagrelor can be considered in lieu of clopidogrel. The 2014 ACC/AHA guidelines recommend ticagrelor as the preferred agent (Class IIa). Prasugrel should only be used in patients undergoing PCI as long as they are not at high risk of bleeding complications.[1]

The use of clopidogrel in NSTE-ACS was evaluated in two studies.[72,73] In the Clopidogrel in Unstable Angina to Prevent Recurrent Ischemic Events (CURE) trial, patients with NSTE-ACS were randomized to placebo plus aspirin (75 to 325 mg) or clopidogrel (300 mg, immediately followed by 75 mg daily) plus aspirin.[72] The composite of cardiovascular death, MI, or stroke was significantly reduced with clopidogrel. However, compared with placebo, an increase in major and minor bleeding was seen. On the basis of these data, clopidogrel with aspirin should be administered immediately on admission and continued ideally for 1 year in patients with ACS.[1]

The PCI-Clopidogrel as Adjunctive Reperfusion Therapy (PCI-CLARITY) study was a planned subanalysis ($n = 1,863$) of the CLARITY-TIMI 28 study (see Case 13-1, Question 9) that evaluated the effects of pretreatment with aspirin plus clopidogrel, compared with aspirin plus placebo, in patients undergoing PCI with coronary artery stenting.[74] Compared with placebo, pretreatment with clopidogrel significantly reduced the incidence of cardiovascular death, MI, or stroke as well as recurrent MI or stroke before PCI with no significant excess in TIMI major or minor bleeding.

CASE 13-2, QUESTION 4: What loading dose should he receive and when should he receive it? What about his maintenance dose?

A loading dose of 600 mg of clopidogrel in patients undergoing PCI achieves greater platelet inhibition with fewer low responders and decreases the incidence of major cardiac events compared with a loading dose of 300 mg.[1] A 300-mg clopidogrel loading dose provides adequate antiplatelet activity in 6 hours whereas a 600-mg clopidogrel loading dose provides antiplatelet activity in 2 hours. Even after a loading dose, clopidogrel requires several hours to be metabolized to its active metabolite. The current guidelines prefer 600 mg because of a greater, more rapid, and more consistent degree of platelet inhibition. Patients undergoing PCI who have previously received a loading dose of 300 mg of clopidogrel and are on a 75-mg daily maintenance dose should receive another 300-mg loading dose. Data do not exist on additional loading doses for patients currently receiving maintenance doses of prasugrel or ticagrelor.

Prasugrel has been evaluated in patients with ACS undergoing PCI. In the Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel–Thrombolysis in Myocardial Infarction (TRITON-TIMI) 38 study, patients with moderate to high-risk ACS, 26% of whom had STEMI, were randomized to prasugrel (60 mg loading dose followed by 10 mg daily) or clopidogrel (300 mg loading dose followed by 75 mg daily).[75] All patients received aspirin (75 to 162 mg daily). The primary outcome of death from cardiovascular causes, nonfatal MI, or nonfatal stroke occurred in 9.9% of patients receiving prasugrel and in 12.1% of patients taking clopidogrel ($p < 0.001$). However, prasugrel was associated with a significant increase in TIMI—major, fatal, and life-threatening bleeding. A post hoc analysis found three subgroups that did not benefit from prasugrel: patients with a history of stroke or TIA, age of 75 years or older, or body weight less than 60 kg. Patients with at least one of these risk factors exhibited a higher rate of bleeding.[76] The Food and Drug Administration (FDA) recommends a 5-mg (rather than 10-mg) maintenance dose be considered for those patients weighing less than 60 kg, even though this dose has not been studied.[77]

In the Study of Platelet Inhibition and Patient Outcomes (PLATO) trial, patients with ACS, with or without ST segment elevation were randomized to receive ticagrelor (180 mg loading dose, 90 mg twice daily thereafter) or clopidogrel (300 to 600 mg loading dose, then 75 mg daily). Compared to clopidogrel, ticagrelor demonstrated a 16% reduced rate of mortality from MI, vascular causes, or stroke ($p < 0.001$) without an increase in the rate of major bleeding but an increased rate in CABG-related bleeding ($p = 0.03$).[78] However, the lowest 1-year rates of cardiovascular death, MI, or stroke were noted in patients with ACS treated with ticagrelor and maintenance low-dose aspirin (≤100 mg/day), whereas the highest rates occurred in those treated with ticagrelor and high-dose aspirin (>300 mg/day).[79] Based on these data, the maintenance dose of aspirin should not exceed 100 mg/day.[80]

When compared with clopidogrel, prasugrel and ticagrelor are more potent, exhibit a lower incidence of stent thrombosis, have fewer drug–drug interactions, and lack variable response based on pharmacogenomics (refer to Chapter 12, Chronic Stable Angina, about responders and nonresponders to clopidogrel). However, many providers have been concerned with the higher risk of bleeding. In the case of J.W., clopidogrel, prasugrel, or ticagrelor could be added, as he does not have a contraindication to any of these drugs. Ticagrelor may be preferred as long as cost is not a concern for the patient.

After PCI with coronary stent deployment with either a drug-eluting or bare metal stent, clopidogrel 75 mg, prasugrel

---

5 to 10 mg, or ticagrelor 90 mg twice daily should be administered for at least 12 months. It is important to highlight that clopidogrel and ticagrelor should be discontinued for 5 days and prasugrel for 7 days, prior to surgery.

As a rapid onset of action is needed, J.W. should receive a loading dose of 600 mg of clopidogrel as soon as possible, followed by 75 mg daily for at least 12 months. If prasugrel is chosen, a loading dose of 60 mg would be given followed by 10 mg daily as long as the patient is >60 kg. For ticagrelor, a loading dose of 180 mg is recommended following by 90 mg twice daily. Aspirin 81 mg daily should be continued indefinitely.

CASE 13-2, QUESTION 5: Should a GP IIb/IIIa inhibitor be added? If so, which one?

In patients with NSTE-ACS, the GP IIb/IIIa inhibitors are of benefit for patients considered high risk, those undergoing PCI, or both.[1] Analysis of GP IIb/IIIa studies suggest that those patients who obtain the greatest advantage from these agents are those who have elevated troponins, diabetes, ST segment changes, or a TIMI risk score of 4 or higher at presentation. The guidelines recommend that for patients with NSTE-ACS who will be treated initially according to an invasive strategy, either a GP IIb/IIIa inhibitor or a $P2Y_{12}$ inhibitor (clopidogrel or ticareglor), should be added to aspirin and anticoagulant therapy before diagnostic angiography is performed.[1] When used to treat patients medically, the GP IIb/IIIa inhibitors tirofiban or eptifibatide are generally given for 18 to 72 hours. Abciximab should be used only with PCI. (Table 13-6).[1]

The GUSTO-IV-ACS trial enrolled patients with NSTE-ACS in whom early (<48 hours) revascularization was not intended. All patients received aspirin and either UFH or LMWH.[81] They were randomized to placebo, abciximab bolus and 24-hour infusion, or abciximab bolus and 48-hour infusion. At 30 days, death or MI occurred in 8.0% of patients receiving placebo, 8.2% of patients receiving 24-hour abciximab, and 9.1% of patients receiving 48-hour abciximab (no significant difference). At 48 hours, death occurred in 0.3%, 0.7%, and 0.9% of patients in these groups, respectively (placebo vs. abciximab at 48 hours; $p = 0.008$). Based on these findings and those of other studies, abciximab is indicated only if angiography will not be appreciably delayed and PCI is likely to be performed; otherwise, IV eptifibatide or tirofiban is preferred (Fig. 13-6).

The guidelines recommend that in the setting of dual antiplatelet therapy used with UFH, the adjunctive use of a GP IIb/IIIa inhibitor administered at the time of PCI cannot be recommended as routine therapy. However, a GP IIb/IIIa inhibitor may be beneficial in those with a large thrombus burden or who have not received adequate $P2Y_{12}$ antagonist loading.[1]

J.W. has a TIMI risk score of 4; therefore, the addition of eptifibatide or tirofiban is a reasonable choice if a large thrombus burden is demonstrated on angiography. Administration prior to PCI ("upstream") is not indicated unless the administration of a $P2Y_{12}$ antagonist is delayed until time of PCI. Platelets and signs and symptoms of bleeding should be monitored closely.

Because J.W. is not at high risk for bleeding, dual antiplatelet therapy in addition to UFH should be adequate therapy. If a large thrombus burden is demonstrated on angiography, a GP IIa/IIIb could be initiated during PCI.

If J.W. had not received an oral $P2Y_{12}$ inhibitor or a GP IIb/IIIa inhibitor, consideration could be given to administering IV cangrelor, a direct-acting $P2Y_{12}$ platelet inhibitor, prior to PCI. Based on the results of the CHAMPION PHOENIX trial, cangrelor could be administered as a 30 mcg/kg bolus followed by a 4 mcg/kg/minute IV infusion for at least 2 hours or for the duration of the PCI.[29] After discontinuation of the infusion, an oral $P2Y_{12}$ inhibitor should be administered (ticagrelor 180 mg load during or upon immediate discontinuation of infusion; prasugrel 60 mg or clopidogrel 600 mg upon immediate discontinuation of infusion) followed by aspirin 81 mg daily along with a maintenance dose of the $P2Y_{12}$ inhibitor. If clopidogrel or prasugrel are administered during the infusion, they will have no antiplatelet effect until the next dose is administered.

CASE 13-2, QUESTION 6: What if an ischemia-driven strategy was decided for J.W. instead, would his antithrombotic therapy change?

Table 13-6

Dosing of Glycoprotein IIb/IIIa in Acute Coronary Syndromes[1,5]

Medication	Dosing for STEMI PCI	Dose for NSTE-ACS With or Without PCI	Comments
Abciximab	0.25 mg/kg IV bolus	Not recommended	

	followed by 0.125 mcg/kg/minute infusion (max of 10 mcg/minute), continue for 12 hours at the discretion of the physician		
Eptifibatide	180 mcg/kg IV bolus, then begin 2 mcg/kg/minute infusion followed by second IV bolus of 180 mcg/kg 10 minutes after first bolus, continue infusion for 12–18 hours after PCI at the discretion of the physician	180 mcg/kg IV bolus, then begin 2 mcg/kg/minute infusion, continue infusion for 12–18 hours Repeat bolus dose after 10 minutes for PCI	Reduce infusion by 50% in patients with CrCl <50 mL/minute; not studied in patients with SCr >4.0 mg/dL; avoid in hemodialysis
Tirofiban	25 mcg/kg IV bolus followed by an infusion of 0.15 mcg/kg/minute, continue up to 18 hours at the discretion of the physician	25 mcg/kg IV bolus within 5 minutes followed by an infusion of 0.15 mcg/kg/minute (or 0.075 mcg/kg/minute for patients with CrCl ≤60 mL/minute), for up to 18 hours.	Reduce infusion by 50% in patients with CrCl < 30 mL/minute

CrCl, creatinine clearance; IV, intravenous; NSTE-ACS, non–ST segment elevation acute coronary syndrome; PCI, percutaneous coronary intervention; SCr, serum creatinine; STEMI, ST segment elevation myocardial infarction.

Management Strategy

ISCHEMIA-GUIDED STRATEGY

An ischemia-guided strategy avoids early invasive procedures, instead relying on the patient's symptoms to direct the need for intervention. Similarly, J.W. would be optimized on anti-ischemic and antithrombotic regimens. At this time, prasugrel and bivalirudin are only indicated in patients undergoing PCI. Additionally, the bleeding risk of GP IIb/IIIa inhibitors outweighs the benefit in this approach and therefore these medications should only be used if PCI is pursued. If during his hospitalization, the patient were to experience any recurrent ischemia, refractory angina despite medical therapy, or high-risk features (e.g., arrhythmias, signs or symptoms of HF, hemodynamic instability, elevated cardiac enzymes), an invasive approach would be pursued.[1]

LONG-TERM THERAPY

Angiotensin-Converting Enzyme Inhibitors, Angiotensin Receptor Blockers, and Direct Renin Inhibitors

CASE 13-3

QUESTION 1: J.S. is a 68-year-old man who presents with a STEMI along with signs and symptoms of HF. His past medical history includes hypertension treated with hydrochlorothiazide 25 mg daily and diabetes for which he takes metformin 500 mg twice daily. He has smoked a pack of cigarettes per day for the past 40 years. On admission, his BP was 145/86 mm Hg, and his heart rate was 90 beats/minute. His weight is 91 kg with a height of 5’9” and a body mass index (BMI) of 29.5 kg/m^2. Laboratory values include the following:

Na, 139 mEq/L
K, 4.2 mEq/L
Cl, 100 mEq/L
CO_2, 20 mEq/L
BUN, 15 mg/dL
SCr, 1.3 mg/dL
Glucose, 130 mg/dL
Hemoglobin A_{1c}, 6.9%
Mg, 2 mEq/L
CK-MB fraction, 35% (normal, 0%–5%)
Troponin I-Ultra, 10 ng/mL (normal, <0.02 ng/mL)

He is administered aspirin 325 mg, prasugrel 60 mg, IV NTG infusion, continuous infusion of UFH, and intranasal oxygen. J.S. is immediately sent to the catheterization laboratory in which he receives a drug-eluting stent in his left anterior descending artery. After stabilization of his HF symptoms, J.S. is started on oral metoprolol tartrate 25 mg every 6 hours. An echocardiogram is performed before discharge and shows an LVEF of 35% along with the appearance of a thrombus in the LV.

Is an ACE inhibitor appropriate for J.S.? When should an ARB be considered?

After an AMI, the heart undergoes processes that initially compensate for the loss of contractile function but may increase the long-term risk for development of HF. This is referred to as remodeling of the ventricle (see Chapter 14, Heart Failure). The increase in the number of survivors of AMI has led to an increase in the number of HF patients. A number of clinical trials with the use of ACE inhibitors have demonstrated reductions in HF symptoms and mortality after MI.[5]

For patients with ACS, oral ACE inhibitor therapy should be started within the first 24 hours of presentation for those with an LVEF of 40% or less (even if asymptomatic) or clinical evidence of HF. Additionally, ACE inhibitors should also be considered for patients with concomitant hypertension, diabetes, and/or chronic kidney disease.[5] The use of IV ACE inhibitor therapy is not recommended. Because of its short half-life, captopril could be given on postinfarction day 2 or 3, beginning with a test dose of 6.25 mg and then titrated as tolerated. Once it is established that the patient can tolerate an ACE inhibitor, he or she can be switched to a once daily agent such as lisinopril to simplify the regimen. The BP should be monitored closely, with systolic BP maintained greater than 90 mm Hg. Renal function and serum potassium levels should be monitored closely during the first few months of therapy. Because J.S. presents with clinical symptoms of HF, he is a candidate for an ACE inhibitor. Additionally, J.S. has an EF of less than 40%, hypertension, and diabetes, therefore the ACE inhibitor should be continued indefinitely (Table 13-2).

If the patient cannot tolerate an ACE inhibitor because of cough, an ARB may be an alternative. In the Optimal Therapy in Myocardial Infarction with the Angiotensin II Antagonist Losartan (OPTIMAAL) trial and Valsartan in Acute Myocardial Infarction Trial (VALIANT), losartan and valsartan demonstrated similar reductions in all-cause mortality compared with captopril.[82,83] Dual therapy of ACE inhibitors with ARBs offers no additional benefits but increases side effects.

Aldosterone Antagonists

CASE 13-3, QUESTION 2: Should J.S. receive an aldosterone antagonist?

Like angiotensin II, aldosterone plays an important role in LV remodeling. Inhibiting aldosterone directly in addition to ACE inhibitor therapy was first evaluated in HF patients in the Randomized Aldactone Evaluation Study (RALES) (see Chapter 14, Heart Failure). Another aldosterone antagonist, eplerenone, is a selective inhibitor of the mineralocorticoid receptor with fewer sexual side effects. In the Eplerenone Post Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS), patients with AMI and EF less than 40% receiving optimal medical therapy were randomized to eplerenone or placebo.[35] Significant reductions in mortality (15%), sudden death (13%), and cardiovascular death or hospitalization (21%) were seen with eplerenone compared to placebo.

The ACC/AHA guidelines recommend an aldosterone antagonist in patients with NSTE-ACS or STEMI who are already receiving therapeutic doses of an ACE inhibitor, have an EF less than 40%, and have either symptomatic HF or diabetes.[1,5] Potential contraindications to the use of an aldosterone antagonist in this setting include significant renal dysfunction (creatinine > 2.5 mg/dL in men, >2.0 mg/dL in women, or creatinine clearance < 30 mL/minute) or hyperkalemia (potassium > 5 mEq/L).

Because J.S. has symptomatic HF with an EF less than 40% and diabetes, he is a candidate for an aldosterone antagonist. Serum potassium and renal function need to be checked in 2 to 3 days and 1 week after therapy initiation, then every month for the first 3 months. ACE inhibitor and potassium supplement doses may need to be adjusted.[84]

β-Blockers

CASE 13-3, QUESTION 3: Should J.S. receive a β-blocker on discharge?

The ACC/AHA guidelines recommend continued β-blocker therapy at discharge for all patients after ACS.[1,5] The benefits of β-blockers in reducing reinfarction and mortality outweigh the risk, even in patients with asthma, depression, insulin-dependent diabetes, severe peripheral vascular disease, first-degree heart block, and moderate LV dysfunction. Atenolol, propranolol, carvedilol, metoprolol tartrate, and metoprolol succinate are generic, making them cost-effective. Metoprolol succinate, carvedilol, and bisoprolol are considered first-line choices in patients with HF, whereas atenolol, metoprolol tartrate, or metoprolol succinate should be considered in patients with stable asthma or bronchospastic pulmonary disease. Being discharged on a β-blocker is a quality performance measure.[85] However, debate exists surrounding the duration of use, especially in low-risk patients without compelling indications.[86–89] Data suggest that the benefits from β-blockers emerge early following an AMI and are maintained out to 1 year. Although the exact duration of benefit is unknown, high-risk patients (e.g., GRACE score ≥ 121 and diuretic use) are likely to continue to derive benefit for up to 3 years. The 2011 AHA/ACCF secondary prevention guidelines recommend a 3-year treatment course for patients with normal LV function, with an option to continue indefinitely as long as the medication is well tolerated. Because J.S. has a low EF, he should be transitioned from oral metoprolol tartrate to metoprolol succinate, carvedilol, or bisoprolol, which should be continued indefinitely.

Lipid-Lowering Agents

CASE 13-3, QUESTION 4: Should J.S. be started on a lipid-lowering agent? If so, which one? When should it be initiated?

A complete fasting lipid profile would be helpful and should be completed within 24 hours of presenting with an AMI.[1,5] This is often overlooked or not done because the patient is not fasting. Most patients will require a low-cholesterol, low-saturated fat diet in addition to lipid-lowering therapy. The ACC/AHA STEMI and NSTE-ACS guidelines recommend that a high-intensity statin therapy be initiated or continued in all patients with ACS unless contraindications are present.[1,5] This would consist of atorvastatin 40 to 80 mg or rosuvastatin 20 to 40 mg daily.[34] When triglycerides are 500 mg/dL or more, drug therapy with niacin or a fibrate is beneficial.[89]

The Myocardial Ischemia Reduction with Aggressive Cholesterol Lowering (MIRACL) trial evaluated NSTE-ACS patients receiving atorvastatin 80 mg/day or placebo within 24 to 96 hours of hospitalization. A significantly lower rate of death and nonfatal major cardiac events at 4 months of follow-up was seen in patients receiving atorvastatin.[90] In the Pravastatin or Atorvastatin Evaluation and Infection Therapy (PROVE-IT)-TIMI 22 trial, patients with ACS who received atorvastatin 80 mg/day for 10 days exhibited a significantly lower risk of death, MI, UA hospitalization, stroke, and revascularization when compared with pravastatin 40 mg/day.[90] The A to Z trial showed a favorable trend toward major cardiovascular event reduction in AMI patients receiving an intensive simvastatin regimen (40 mg/day for 1 month followed by 80 mg/day thereafter) when initiated within 12 hours of stabilization compared to a less intensive regimen (placebo for 4 months followed by simvastatin 20 mg/day).[91] However, based on clinical trials, observational studies, adverse event reports, and prescription use data, simvastatin 80 mg may be associated with increased muscle injury (refer to Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease).[34]

In the case of J.S., he should receive a high-intensity statin within 24 hours of his hospitalization and be discharged on a statin regardless of LDL cholesterol. This is a quality core performance measure.[85] Drug interactions, patient tolerability, and affordability should be considered. Currently, the LDL goal for patients with ACS remains controversial. The ACC/AHA STEMI and NSTE-ACS guidelines do not recommend a specific goal LDL. However, the National Lipid Association does recommend a goal LDL less than 100 mg/dL in patients with ACS.[92] For J.S. it would be reasonable to begin atorvastatin 80 mg daily and obtain an LDL of less than 100 mg/dL or a reduction of 50%.

Antiplatelet Therapy

CASE 13-3, QUESTION 5: How long should J.S. continue his aspirin and prasugrel?

Antiplatelet therapy with aspirin should be lifelong for J.S. because of aspirin's beneficial effects on reinfarction. There appears to be no difference in efficacy for a wide range of aspirin doses (75–1,500 mg/day), although higher doses may increase the incidence of side effects. The ACC/AHA guidelines recommend a dose of 81 to 325 mg daily indefinitely with a preferred maintenance dose of 81 mg daily.[1,5] Dual antiplatelet therapy with clopidogrel or ticagrelor and aspirin, compared with aspirin alone, reduces major cardiovascular events in patients with established ischemic heart disease.[93,94] The use of dual antiplatelet therapy with a $P2Y_{12}$ inhibitor for patients who have undergone coronary stenting reduces the risk of future stent thrombosis.[1,5] In ACS patients, ideally the $P2Y_{12}$ inhibitor should be continued for at least 1 year regardless of the type of coronary stent. Data from the Dual Antiplatelet Therapy (DAPT) trial found that dual antiplatelet therapy with clopidogrel or prasugrel continued for 30 months after placement of a drug-eluting stent significantly reduced the risk of stent thrombosis and major adverse cardiovascular and cerebrovascular events compared with 12 months of therapy, but was associated with an increased risk of bleeding.[95]

Because J.S. underwent PCI and received a coronary stent, his dose of aspirin will be 81 mg daily indefinitely. He should continue prasugrel 10 mg daily for at least 1 year. Aspirin should be prescribed at hospital discharge because it is a quality performance measure.[85]

CASE 13-3, QUESTION 6: If J.S. had received ticagrelor instead of prasugrel, how would his ticagrelor and aspirin been dosed?

In the Patients with Prior Heart Attack Using Ticagrelor Compared to Placebo on a Background of Aspirin–Thrombolysis in Myocardial Infarction 54 (PEGASUS TIMI-54) study, 21,162 patients who had an AMI 1 to 3 years earlier were randomized to ticagrelor 90 mg twice daily, ticagrelor 60 mg twice daily, or placebo plus low-dose aspirin.[94] Compared to placebo plus low-dose aspirin, both ticagrelor doses significantly reduced the rate of the composite of cardiovascular death, MI, or stroke with a 3-year rate of 7.85% in the group that received 90 mg of ticagrelor twice daily, 7.77% in the group that received 60 mg of ticagrelor twice daily, and 9.04% in the placebo group. Therefore, if J.S. were to receive ticagrelor, then he would have received 180 mg load following his ACS event, then 90 mg twice daily during the first year, then 60 mg twice daily after the first year for up to 3 years.[80] Aspirin 325 mg would be given on day 1 of his ACS event followed by 81 mg daily indefinitely.

Warfarin

CASE 13-3, QUESTION 7: Three days before J.S.'s anticipated discharge, the medical team is discussing the need to administer long-term warfarin in addition to his dual antiplatelet therapy with aspirin and prasugrel. Is warfarin indicated for J.S. at this time?

p. 258

---

p. 259

Long-term warfarin may be beneficial in some patients, but clinical judgment is needed to decide whether the benefit is likely to exceed the risk. Data suggest that the incidence of a LV thrombus and atrial fibrillation occurs between 7% to 46% and 2% to 22% respectively in patients following an AMI.[96,97] The ACC/AHA guidelines recommend warfarin for ACS patients with atrial fibrillation, mechanical heart valves, venous thromboembolism, hypercoagulable disorder, and LV mural thrombus.[5] In patients already receiving dual antiplatelet therapy, the guidelines recommend limiting the duration of triple antithrombotic therapy to minimize the risk of bleeding. Consideration can also be given to targeting a goal international normalized ratio (INR) of 2.0 to 2.5 for those patients whose usual goal INR is between 2.0 and 3.0; however, no prospective studies have demonstrated that a target

INR of 2.0 to 2.5 reduces bleeding complications.[1,5] In the What is the Optimal Antiplatelet and Anticoagulant Therapy in Patients With Oral Anticoagulation and Coronary Stenting (WOEST) trial, use of clopidogrel without aspirin was associated with a significant reduction in bleeding complications and no increase in thrombotic events compared to clopidogrel with aspirin in patients undergoing PCI who were receiving oral anticoagulation.[98]

Triple antithrombotic therapy has limited information with the use of newer $P2Y_{12}$ inhibitors (prasugrel, ticagrelor); the DTI (dabigatran); or factor Xa inhibitors (rivaroxaban, apixaban, and edoxaban). Prasugrel and ticagrelor can produce a greater degree of platelet inhibition than clopidogrel and are associated with greater rates of bleeding. Therefore, caution is required when using these agents in patients who require an anticoagulant or who are at significantly increased risk of bleeding.[1]

In the case of J.S., due to the presence of a LV thrombus, he is probably a good candidate for 1 to 3 months of warfarin therapy titrated to an INR of 2 to 2.5. His dose of aspirin should be 81 mg/daily if warfarin is prescribed. It would also be reasonable to consider clopidogrel instead of prasugrel in J.S.

Proton-Pump Inhibitor

CASE 13-3, QUESTION 8: Should J.S. receive a proton-pump inhibitor (PPI)?

The ACC/AHA/American College of Gastroenterology recommend using a PPI in patients receiving dual antiplatelet therapy who have multiple risk factors for gastrointestinal bleeding such as advanced age; concomitant use of warfarin, steroids, or NSAIDs; or Helicobacter pylori infection.[99] The ACC/AHA NSTE-ACS guidelines recommend the use of a PPI in patients with a history of gastrointestinal bleeding who are receiving triple antithrombotic therapy (Class I) and for those without a history of gastrointestinal bleeding receiving triple antithrombotic therapy (Class IIa).[99] Because omeprazole and esomeprazole are known to inhibit the isoenzyme 2C19, the FDA recommends against the use of these with clopidogrel because of the possible reduced effectiveness of clopidogrel.[1,100] If J.S. receives triple antithrombotic therapy with prasugrel, any PPI can be used.

CASE 13-3, QUESTION 9: How would you summarize the long-term therapy needed by J.S. on discharge?

Appropriate discharge medications for J.S. include a β-blocker, ACE inhibitor, aldosterone antagonist, aspirin 81 mg/day, $P2Y_{12}$ inhibitor, PPI, and warfarin to achieve an INR of 2 to 2.5. He also should receive a prescription for sublingual NTG to carry with him for use as needed. These agents should be continued long term except for warfarin, which should be discontinued after a few months if his LV thrombus has resolved. Continuation of the $P2Y_{12}$ inhibitor beyond 1 year may be considered after careful assessment of the patient’s ischemic and bleeding risk. J.S.

should be started on a statin to achieve an LDL goal of less than 100 mg/dL or a 50% reduction from his baseline value. Routine liver function tests should be obtained before initiation of therapy and periodically thereafter. His previous hydrochlorothiazide may be discontinued because his hypertension will likely be controlled with the β-blocker, ACE inhibitor, and aldosterone antagonist. His metformin should be continued, and his blood glucose monitored closely. As J.S. will have several new medications, he will need education regarding his medications prior to discharge in order to optimize medication adherence.

LIFESTYLE MODIFICATIONS

CASE 13-3, QUESTION 10: What types of lifestyle modifications should J.S. be encouraged to pursue to reduce his risk factors?

J.S. must be encouraged to stop smoking; this may be the most important change he can make (see Chapter 91, Tobacco Use and Dependence).[101] For weight management, an initial goal weight loss should be to reduce body weight by approximately 10% from baseline if BMI exceeds 25 kg/m^2.[89] Other dietary modifications should be implemented so that J.S. can maintain a hemoglobin A_{1c} less than 7.0% and achieve a BP goal of less than 140/90 mm Hg (or possibly lower) because J.S. has diabetes, and a serum LDL less than 100 mg/dL.[89,102,103] (See Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease; Chapter 9, Essential Hypertension; and Chapter 12, Chronic Stable Angina, for further information on antihypertensive and lipid-lowering drugs, as well as, diet therapy.)

SUMMARY

Although mortality and incidence rates for ACS appear to be on the decline, ACS still remains a major cause of morbidity and mortality in the United States. The use of PCI has significantly improved the survival of patients with STEMI. The major risk associated with thrombolysis is bleeding, especially intracerebral hemorrhage. Another problem associated with fibrinolytic therapy is reocclusion of the artery that was initially opened. PCI is more effective than fibrinolytic therapy; however, it is available only in hospitals with experienced invasive cardiologists, thereby limiting its availability to some patients.

Aspirin should be given to all patients with ACS; unless there is a contraindication, β-blockers and statins should be administered as well. $P2Y_{12}$ inhibitors are recommended with aspirin in all patients with ACS with or without stenting. ACE inhibitors, ARBs, and aldosterone antagonists have been shown to be beneficial in patients who have LV dysfunction (LVEF < 40%) and are also recommended for secondary prevention. Nitrates are useful, but care must be taken to maintain an adequate perfusion pressure. Secondary prevention emphasizing a healthy lifestyle and aggressive lipid lowering are important components to the overall treatment plan.

Heart Failure

Harleen Singh and Joel C. Marrs

	CORE PRINCIPLES	CHAPTER CASES
1	Heart failure (HF) “is a complex clinical syndrome that can result from any structural or functional cardiac disorder that impairs the ability of the ventricle to fill with or eject blood.” This is further subdivided into HF with reduced left ventricular ejection fraction (HFrEF) or HF with preserved left ventricular ejection fraction (HFpEF), previously known as diastolic HF.	**Case 14-1 (Question 1)**
2	HF symptoms, including limitations in activity, can be quantified with the use of the New York Heart Association functional classification system and the American College of Cardiology–American Heart Association classification of chronic HF. The cardinal signs and symptoms (e.g., peripheral edema, dyspnea, fatigue) of HF must be evaluated in light of the patient’s medical history, physical examination, and results of additional testing.	**Case 14-1 (Questions 2, 3)**
3	Coexisting medical conditions that lead to HF (e.g., ischemic heart disease, hypertension, atrial fibrillation [AF], diabetes mellitus, sleep apnea) or result from HF (e.g., AF, cachexia, depression) may influence the overall prognosis and treatment; therefore, these should be assessed on a routine basis.	**Case 14-1 (Question 4),** **Case 14-2 (Question 7),** **Case 14-5 (Question 3)**
4	Several categories of medications (such as nonsteroidal antiinflammatory drugs and “glitazones”) may exert unfavorable hemodynamic effects and may precipitate HF symptoms in patients with previously compensated HF. In some patients, the occurrence of HF can be attributed to the cardiotoxic effect of a particular medication (cancer chemotherapeutic drugs).	**Case 14-1 (Question 5)**
5	Treatment goals are to improve symptoms, decrease hospitalizations, and prevent premature death in patients. The cornerstone of treatment for HFrEF is to optimize life-prolonging therapies (e.g., angiotensin-converting enzyme inhibitors, angiotensin receptor blocking agents, β-blockers, aldosterone antagonists) and promote healthy lifestyle choices (e.g., sodium restriction, exercise training).	**Case 14-1 (Questions 6–20),** **Case 14-2 (Questions 1–8),** **Case 14-3 (Questions 1,2)**
6	Prompt recognition of symptoms and appropriate treatment are critical in the management of acute decompensated HF. The mainstay of therapy in patients with volume overload is an intravenous loop diuretic. Other therapies (e.g., inotropic drugs) have failed to show long-term benefits	**Case 14-4 (Questions 1–3),** **Case 14-5 (Questions 1, 2)**

	in clinical trials.	
⑦	An implantable cardioverter-defibrillator reduces the risk of sudden cardiac death in patients with reduced left ventricular function. Cardiac resynchronization therapy can be used in combination to improve symptoms and quality of life in patients with severe HF symptoms.	**Case 14-5 (Question 4),** **Case 14-6 (Questions 1, 2)**
⑧	There is little clinical trial evidence to guide which treatments are optimal to use in HFpEF.	**Case 14-7 (Question 1)**

⑨	Although controversial, certain patients may respond differently to drug therapy (e.g., African American patients, women).	**Case 14-2 (Question 3),** **Case 14-3 (Question 2)**
⑩	HF is an extremely serious condition and requires careful diagnosis, ongoing monitoring, and the implementation of evidence-based therapy. Herbal remedies (e.g., hawthorn) have some evidence to support their role in improving symptoms of HF; however, they have no evidence demonstrating improvements in mortality. Herbals can also potentially interact with other heart medications.	**Case 14-8 (Question 1)**

Heart failure (HF) is “a complex clinical syndrome that results from any structural or functional cardiac impairment of ventricle filling or ejection of blood.”[1] Congestive heart failure (CHF) is a subset of HF characterized by left ventricular (LV) systolic dysfunction and volume excess. However, some patients may lack symptoms of congestion and still have reduced cardiac output (CO) manifesting as fatigue and reduced exercise tolerance. Therefore, the term CHF has been replaced with HF.

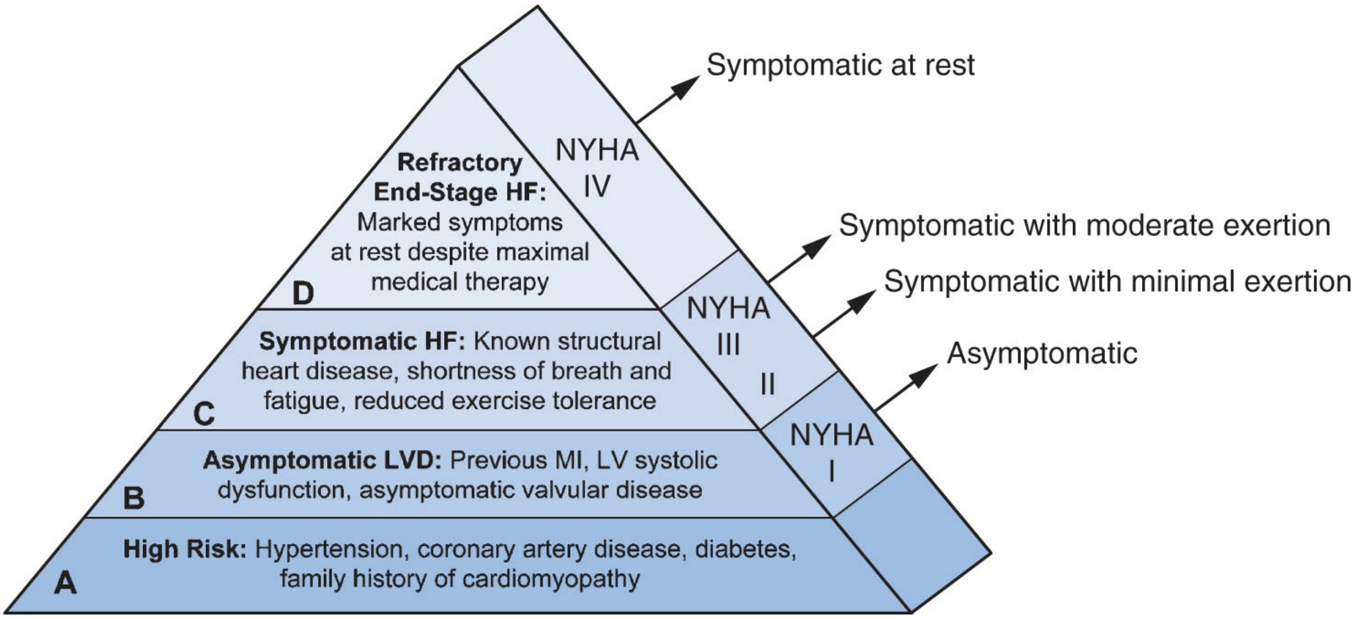
The descriptive terminology, diagnostic techniques, and treatment of HF have undergone significant change in the past 20 years. Since 1994, a series of consensus and evidence-based practice guidelines have been published in an effort to standardize HF management. Guidelines from the Heart Failure Society of America,[2] American College of Cardiology (ACC), American Heart Association (AHA),[1] and the European Society of Cardiology[3] have been revised and updated to reflect ongoing changes in the management of HF. These guidelines use the four disease stages of HF first assigned by the ACC/AHA 2001 guidelines (Fig. 14-1).[4] This classification promotes the early identification of risk factors that are associated with the development of LV dysfunction and HF symptoms. It emphasizes that appropriate therapeutic interventions in the early stages (stages A and B) can prevent progression to overt HF symptoms. It does not replace the New York Heart Association (NYHA) functional classification, but reinforces that they should be used in combination to classify patients. The ACC/AHA guidelines[1,5,6] provide a comprehensive review on prevention, diagnosis, risk stratification, and treatment of HF in both outpatient and inpatient settings. The updates emphasize quality of care and adherence to performance measures. The terminology "guideline-directed therapy" (GDMT) is frequently used in lieu of optimal medical therapy.

Numerous programs and systems have been implemented in an attempt to decrease the cost and length of hospital stay for HF. It is recommended that practitioners look at least annually for the most recently published guidelines to be aware of the rapidly evolving treatment strategies for HF.

Incidence, Prevalence, and Epidemiology

It is estimated that there are 5.7 million people (1.5%–2% of the population) with HF in the United States, and approximately 23 million people with HF worldwide. The prevalence of HF continues to increase, with an estimated 46% increase in prevalence by 2030.[7] Every year, 870,000 people have a new diagnosis of HF, and at 40 years of age, one in five have a lifetime risk of developing this syndrome. After age 65, HF incidence approaches 10 per 1,000 person-years and is the most common cause of hospitalizations in the elderly population in the United States.

The incidence of HF is greater in men and in the elderly; however, the incidence in black women is as high as that in white men. In women, coronary artery disease (CAD) and diabetes are considered the strongest risk factors for HF. African Americans present with HF at a younger age compared with white individuals. Risk factors, such as ischemic heart disease, hypertension (HTN), smoking, obesity, and diabetes, among others, have been identified that predict the incidence of HF as well as its severity.[7]



Symptomatic at rest
NYHA IV
Refractory End-Stage HF: Marked symptoms at rest despite maximal medical therapy
D
Symptomatic with moderate exertion
Symptomatic with minimal exertion
NYHA III
II
Symptomatic HF: Known structural heart disease, shortness of breath and fatigue, reduced exercise tolerance
C
Asymptomatic
NYHA I
Asymptomatic LVD: Previous MI, LV systolic dysfunction, asymptomatic valvular disease
B
High Risk: Hypertension, coronary artery disease, diabetes, family history of cardiomyopathy

Figure 14-1 Staging and New York Heart Association (NYHA) classification of heart failure. (From Hunt SA et al. ACC/AHA Guidelines for the Evaluation and Management of Chronic Heart Failure in the Adult: Executive Summary. A Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to Revise the 1995 Guidelines for the Evaluation and Management of Heart Failure): Developed in Collaboration With the International Society for Heart and Lung Transplantation; Endorsed by the

Heart Failure Society of America. Circulation. 2001;104:2996.)

In 2011, one in nine deaths has HF mentioned on the death certificate.[7] Evidence from national databases and community-based cohorts indicates that the incidence of HF seems to be stabilizing, if not decreasing, for women, and that the length of survival in patients with HF is increasing. However, the death rate remains high; almost 50% of people diagnosed with HF will die within 5 years.[5] The mortality risk steadily increases each year after the diagnosis of HF. The 6-month mortality rates are no different in patients with preserved versus reduced LV ejection fraction (EF).[8] Direct and indirect health care costs of HF in 2012 were estimated to be $30.7 billion.[7]

Various risk prediction models have been developed to predict HF outcomes. Given the heterogeneous nature of the HF population (ischemic vs. nonischemic, low vs. preserved EF), and multiple comorbid conditions, the validity of the risk prediction models is not consistent in all HF populations. Therefore, it is important to identify patients who are at high risk of HF and how various risks factors can predict outcomes.[9] Based on the strength of these associations, prevention measures need to be designed to decrease HF hospitalizations in targeted subpopulations. The 2013 guidelines[1] emphasize that validated multivariable risk scores can be useful to estimate subsequent risk of mortality in ambulatory or hospitalized patients with HF.

Etiology

LOW-OUTPUT VERSUS HIGH-OUTPUT FAILURE

HF has been described as being either low-output or high-output failure, with a predominance of cases being low-output failure (Table 14-1). In both types, the heart cannot provide adequate blood flow (tissue perfusion) to meet the body's metabolic demands, especially during exercise. The hallmark of classic low-output HF is a diminished volume of blood being pumped by a weakened heart in patients who have normal metabolic needs.

In high-output failure, the heart is healthy and pumps a normal or even higher than normal volume of blood. Because of high metabolic demands caused by other underlying medical disorders (e.g., hyperthyroidism, anemia), the heart becomes exhausted from the increased workload and eventually cannot keep up with demand. The primary treatment of high-output HF is amelioration of the underlying disease. Unless otherwise stated, this chapter focuses on the treatment of low-output HF.

LEFT VERSUS RIGHT VENTRICULAR DYSFUNCTION

Low-output HF is further divided into left and right ventricular dysfunction, or a combination of the two (biventricular failure). Because the left ventricle is the major pumping chamber of the heart, left ventricular dysfunction is the most common form of low-output HF and the major target for pharmacologic intervention. Right ventricular dysfunction may coexist with LV HF if damage is sustained by both sides of the heart or as a delayed complication of progressive left-sided HF.

Isolated right-sided ventricular dysfunction, which is relatively uncommon, is usually caused by either primary or secondary pulmonary arterial hypertension. In these conditions, elevated pulmonary artery pressure impedes emptying of the right ventricle, thus increasing the workload on the right side of the heart.[10,11] Primary pulmonary arterial HTN is idiopathic, caused by increased resistance of the pulmonary arterial vasculature of unknown etiology. Secondary causes of pulmonary HTN include collagen vascular disorders, sarcoidosis, fibrosis, exposure to high altitude, and drug and chemical exposure. Drug-induced causes include opioid overdoses (especially heroin), 5-hydoxytryptamine-2B (5HT-2B) agonists (e.g., dexfenfluramine, fenfluramine, and pergolide), and pulmonary fibrosis caused by intravenous (IV) injection of poorly soluble forms of methylphenidate. Right-sided heart disease that occurs as a result of a pulmonary process is known as cor pulmonale.

Table 14-1

Classification and Etiology of Left Ventricular Dysfunction

Type of Failure	Characteristics	Contributing Factors	Etiology
Low output, systolic dysfunction (dilated cardiomyopathy)[a]	Hypofunctioning left ventricle; enlarged heart (dilated left ventricle); ↑left ventricular end-diastolic volume; EF <40%; ↓stroke volume; ↓CO; S_3 heart sound present	1. ↓Contractility (cardiomyopathy) 2. ↑Afterload (elevated SVR)	1. Coronary ischemia,[b] MI, mitral valve stenosis or regurgitation, alcoholism, viral syndromes, nutritional deficiency, calcium and potassium depletion, drug induced, idiopathic 2. Hypertension, aortic stenosis, volume overload
Diastolic dysfunction	Normal left ventricular contractility; normal size heart; stiff left ventricle; impaired left ventricular relaxation; impaired left ventricular filling; normal EF; S_4 heart sound	1. Thickened left ventricle (hypertrophic cardiomyopathy) 2. Stiff left ventricle (restrictive cardiomyopathy) 3. ↑Preload	1. Coronary ischemia,[b] M hypertension, aortic stenosis and regurgitation, pericarditis, enlarged left ventricular septum (hypertrophic cardiomyopathy) 2. Amyloidosis, sarcoidosis

			3. Sodium and water retention
High-output failure (uncommon)	Normal or ↑contractility; normal size heart; normal left ventricular end-diastolic volume; normal or ↑EF; normal or increased stroke volume; ↑CO	1. ↑Metabolic and oxygen demands	1. Anemia and hyperthyroidism

[a] Same as congestive heart failure if symptoms also present.

[b] Heart failure caused by coronary artery ischemia or myocardial infarction classified as ischemic etiology. All other types combined classified as nonischemic.

CO, cardiac output; EF, ejection fraction; MI, myocardial infarction; SVR, systemic vascular resistance.

SYSTOLIC VERSUS DIASTOLIC DYSFUNCTION; ISCHEMIC VERSUS NONISCHEMIC HEART FAILURE

LV dysfunction is further subdivided into systolic and diastolic dysfunction, with mixed disorders also being encountered (Table 14-1). In systolic dysfunction, the stroke volume (SV) (the volume of blood ejected with each contraction; normal, 60–130 mL) and the subsequent CO (SV × heart rate; normal, 4–7 L/minute) are reduced. In diagnosing HF, a critical marker differentiating systolic from diastolic dysfunction is the left ventricular ejection fraction (LVEF), defined as the percentage of LV end-diastolic volume expelled during each systolic contraction (normal, 60%–70%).

In systolic dysfunction, the LVEF is less than 40%, dropping to less than 20% in advanced HF. Heart failure with reduced ejection fraction (HFrEF) is a result of factors causing the heart to fail as a pump (decreased myocardial contractility). The heart dilates as it becomes congested with retained blood, leading to an enlarged hypokinetic left ventricle.

HF caused by coronary ischemia or after MI is classified as ischemic, with all other types grouped as nonischemic. CAD is a common cause of HF in patients with LV systolic dysfunction. Other causes of LV pump failure include persistent arrhythmias, poststreptococcal rheumatic heart disease, chronic alcoholism (alcoholic cardiomyopathy), viral infections, or unidentified etiology (idiopathic dilated cardiomyopathy). Chronic HTN, as well as cardiac valvular disorders (aortic or mitral stenosis), also precipitate systolic HF by increasing resistance to CO (a high afterload state).

In contrast, LV diastolic dysfunction refers to impaired relaxation and increased stiffness of the left ventricle; the EF may or may not be abnormal, and the patient may or may not be symptomatic. Some patients have both systolic and diastolic dysfunction. The term heart failure with normal or preserved left ventricular ejection fraction (HFpEF) is used for patients who have symptoms of HF but a normal EF. These patients always have diastolic dysfunction.

Possible causes of diastolic dysfunction include: coronary ischemia, chronic uncontrolled HTN, LV wall scarring after an MI, ventricular wall hypertrophy, hypertrophic cardiomyopathy, restrictive cardiomyopathy (amyloidosis and sarcoidosis), and valvular heart disease (aortic stenosis). These factors lead to LV wall stiffness (reduced wall compliance), and inability of the ventricle to relax during diastole, which result in an elevated pressure within the ventricle despite a relatively low volume of blood. In turn, the elevated pressure impedes LV filling during diastole that would normally occur by passive inflow against a low-resistance pressure gradient. Heart size is usually (but not always) normal. It is estimated that 20% to 60% of patients with HF may have normal LVEF and reduced ventricular compliance.[12] Because coronary ischemia, MI, and HTN are contributors to both systolic and diastolic dysfunction, many patients have both systolic and diastolic dysfunction.

The pathology of systolic dysfunction most closely resembles what has historically been called "congestive heart failure." Tremendous variability exists in the clinical presentation of both systolic and diastolic dysfunction; however, both disorders can have similar symptoms.[4,11] Most patients exhibit exercise intolerance and shortness of breath (SOB) with either systolic or diastolic dysfunction. Some exhibit significant edema, whereas others may have no edema or symptoms of congestion. It is possible to be asymptomatic in the early stages of HF. For all these reasons, it is best to avoid the abbreviation CHF, because not all patients have congestion. CHF has also been used to denote "chronic heart failure." Clinicians are strongly encouraged to obtain an EF measurement in all patients. The diagnosis of HF should be based on a combination of symptoms and signs together with appropriate clinical tests.

CARDIAC WORKLOAD

A common finding of HF is increased cardiac workload. Four major determinants contribute to LV workload: preload, afterload, contractility, and heart rate (HR).

Preload

Preload describes forces acting on the venous side of the circulation affecting myocardial wall tension. The volume is maximal when filling finishes at the end of diastole (LV end-diastolic volume). An increased volume raises the pressure within the ventricle (LV end-diastolic pressure), which in turn increases the "stretch," or wall tension, of the ventricle. Peripheral venous dilation and decreased peripheral venous volume diminish preload, whereas peripheral venous constriction and increased peripheral venous volume increase preload.

Elevated preload can aggravate HF. Rapid administration of blood plasma expanders and osmotic diuretics or administration of large amounts of sodium or sodium-retaining agents increase preload. A malfunctioning aortic valve (aortic insufficiency), resulting in regurgitation of blood back into the left ventricle, can increase the volume of blood that must be pumped. A malfunctioning mitral valve (mitral regurgitation) can cause retrograde ejection of blood from the left ventricle back into the left atrium, with a resultant decrease in CO. In patients with systolic failure, ventricular blood is ejected less efficiently because of a hypofunctioning left ventricle; the volume of blood retained in the ventricle is thus increased, and preload becomes elevated. In HFpEF with a stiffened left ventricle, relatively small increases in end-diastolic volume from sodium and water overload can lead to exaggerated increases in end-diastolic pressure.

Afterload

Afterload is the tension developed in the ventricular wall as contraction (systole) occurs. This tension is affected by intraventricular pressure, ventricular diameter, and wall thickness. Afterload is affected by the systemic vascular resistance (SVR) or the impedance against which the ventricle must pump and is estimated by arterial blood pressure (BP). HTN, atherosclerotic disease, or a narrow aortic valve opening, increases arterial impedance (afterload), thereby increasing the workload of the heart. HTN is a major factor in the development of both HFrEF and HFpEF. The Framingham group found that 75% of patients who developed HF had a history of HTN.[13] The risk of developing HF was six times greater in hypertensive versus normotensive patients.

Cardiac Contractility

The terms contractility and inotropic state are used synonymously to describe the myocardium's ability to develop force and shorten its fibers independent of preload or afterload. Myocardial contractility is decreased when myocardial fibers are diminished or poorly functioning as may occur in patients with primary cardiomyopathy, valvular heart disease, CAD, or after a myocardial infarction (MI). Defects in contractility play a major role in systolic HF, but are not a factor for diastolic dysfunction. Drugs such as β-adrenergic blockers or anthracyclines precipitate HF by decreasing myocardial contractility.

Heart Rate

An increased HR is a reflex mechanism to improve CO as EF declines. The sympathetic nervous system is the major mediator of this response. The workload and energy demands of a rapid HR ultimately place strain on the heart and can eventually worsen HF.

Pathophysiology

When the heart begins to fail, the body activates several complex compensatory mechanisms in an attempt to maintain CO and oxygenation. These include increased sympathetic tone, activation of the renin–angiotensin–aldosterone system (RAAS), sodium and water retention, and other neurohormonal adaptations, which lead to cardiac "remodeling" (ventricular dilatation, cardiac hypertrophy, and changes in LV shape). The consequences of these adaptive mechanisms can create more harm than good (Fig. 14-2). The relative balance of each of these adaptive processes varies depending on the type of HF (systolic versus diastolic dysfunction) and from patient to patient with the same disorder. An understanding of the potential benefits and adverse consequences of these compensatory mechanisms is essential to understanding the signs, symptoms, and treatment of HF.[14]

SYMPATHETIC (ADRENERGIC) NERVOUS SYSTEM

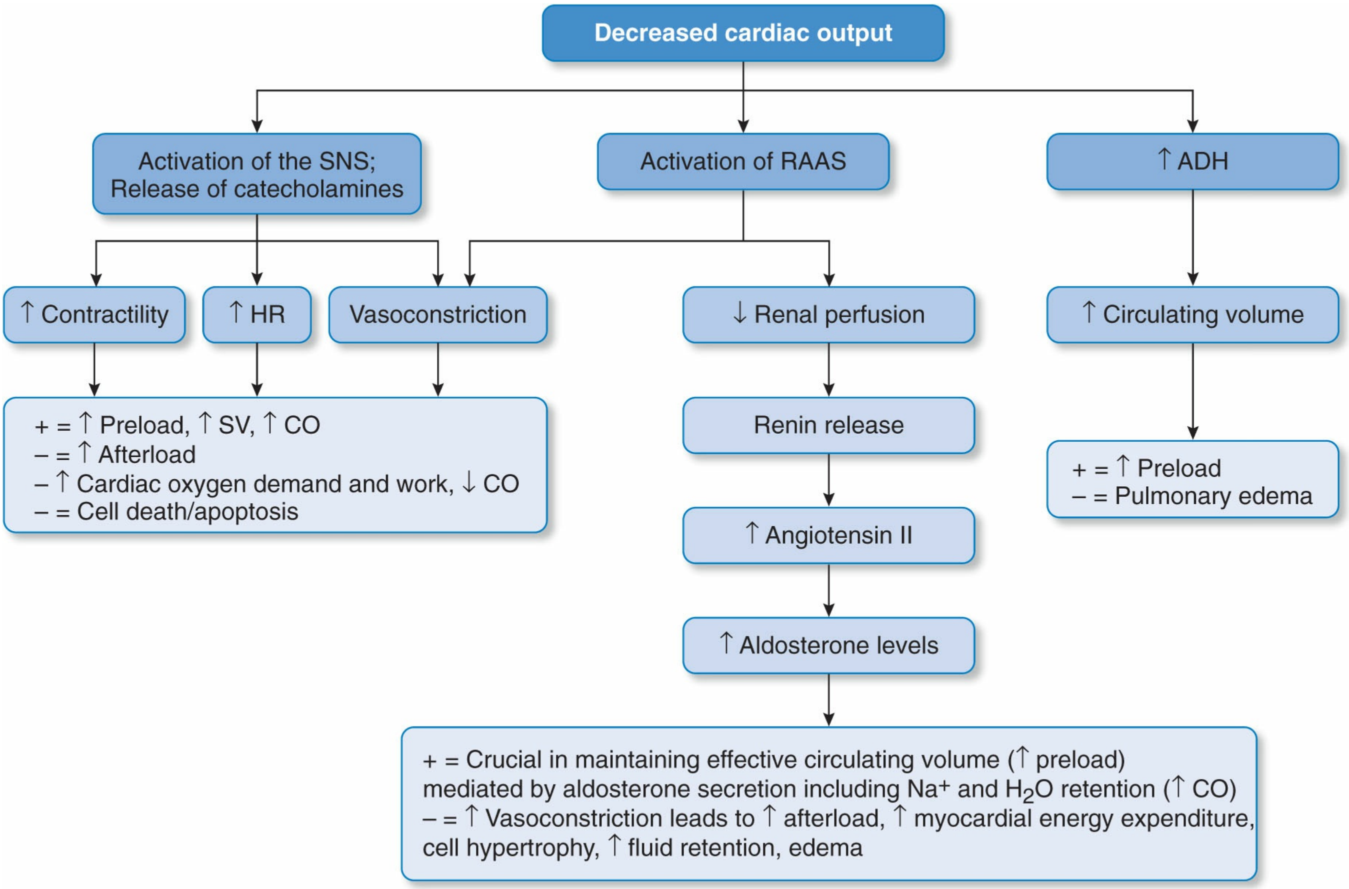
The body's normal physiologic response to a decreased CO is generalized activation of the adrenergic (sympathetic) nervous system as evidenced by increased circulating levels of norepinephrine (NE) and other catecholamines. The inotropic (increased contractility) and chronotropic (increased HR) effects of NE initially maintain near-normal CO and perfusion of vital organs such as the central nervous system (CNS) and myocardium. Adverse consequences of NE activation include impaired sodium excretion by the kidneys, restricted ability of the coronary arteries to supply blood to the ventricle (myocardial ischemia), increased arrhythmias, hypokalemia, and oxidative stress triggering cell death (apoptosis).

Chronic high levels of catecholamines are harmful to the heart because they decrease β_1-receptor sensitivity and reduce β_1-receptor density on the surface of myocardial cells by 60% to 70% in severe HF.[14–20] The normal ratio of β_1- to β_2-receptors in the heart is ˜80:20. As a response to overstimulation, this balance is shifted to a ratio of ˜70:30 in the failing myocardium by downregulation of β_1-subtype receptors. This selective downregulation of β_1-receptors is accompanied by "uncoupling of the β_1- and β_2-receptor activity," whereby the number of β_2-receptors is unchanged but the responsiveness of these receptors can be reduced by 30%.[15] Over time, this leaves the myocyte less responsive to adrenergic stimuli and further decreases contractile function. β-Blockers cause the upregulation of the downregulated β_1 receptors and, the re-sensitization of the uncoupled β_2-receptors protecting the heart from the deleterious effects of catecholamines.[21]

Alterations in sympathetic adrenergic receptors are partially determined by genetic phenotype. Among African American patients with HF, a disproportionately high incidence of polymorphisms for variants of the β_1-receptor that are associated with increased function is seen. Additionally, the combined presence of a variant of the β_1-receptor (β_1Arg389) and α_{2C}-adrenergic receptor (α_{2c}Del322–325) results in adrenergic overstimulation and increases the risk of HF. These combined defects are found less often in whites, perhaps partially explaining a higher incidence of HF in African Americans. A better understanding of α- and β-receptor phenotypes may someday lead to improved prevention and treatment of HF.[22]

RENAL FUNCTION AND THE RENIN–ANGIOTENSIN–ALDOSTERONE SYSTEM

The reduced CO in HF leads to the stimulation angiotensin II, which is a potent vasoconstrictor. Angiotensin II is also a potent stimulator of the sympathetic nervous system, which increases SVR. Renal vascular resistance is increased, and the glomerular filtration rate (GFR) is decreased. As the GFR decreases, more sodium and water are reabsorbed. A diminished effective circulating plasma volume and angiotensin II also stimulate release of antidiuretic hormone (ADH) from the pituitary, resulting in the retention of free water in the collecting ducts.



Decreased cardiac output
Activation of the SNS; Release of catecholamines
Activation of RAAS
↑ ADH
↑ Contractility
↑ HR
Vasoconstriction
↓ Renal perfusion
↑ Circulating volume
+ = ↑ Preload, ↑ SV, ↑ CO

– ↑ Cardiac oxygen demand and work, ↓ CO
– = Cell death/apoptosis
Renin release
+ = ↑ Preload
– = Pulmonary edema
↑ Angiotensin II
↑ Aldosterone levels
+ = Crucial in maintaining effective circulating volume (↑ preload) mediated by aldosterone secretion including Na^+ and H_2O retention (↑ CO)
– = ↑ Vasoconstriction leads to ↑ afterload, ↑ myocardial energy expenditure, cell hypertrophy, ↑ fluid retention, edema

Figure 14-2 Adaptive mechanisms in systolic heart failure. +, beneficial results; –, negative (detrimental) effects; ADH, antidiuretic hormone; CO, cardiac output; HR, heart rate; H_2O, water; Na^+, sodium; RAAS, renin–angiotensin–aldosterone system; SNS, sympathetic nervous system; SV, stroke volume.

The kidney releases renin when renal perfusion pressure is decreased. Renin converts angiotensinogen into angiotensin I. Angiotensin I is metabolized to angiotensin II, under the influence of angiotensin-converting enzyme (ACE) (Fig. 14-2). Angiotensin II has multiple effects favoring sodium and water retention. Its vasoconstricting effect decreases GFR, and it stimulates the adrenal glands to secrete aldosterone, which increases sodium reabsorption. Angiotensin II stimulates increased synthesis and release of vasopressin, thereby increasing free water retention and stimulation of thirst centers in the CNS. Finally, angiotensin II stimulates NE release. The net result of decreased renal perfusion is detrimental. Increased sodium and water retention increase preload, whereas angiotensin II–induced vasoconstriction increases SVR and afterload.

A chronic excess of aldosterone causes fibrosis in the myocardium, kidneys, and other organs.[23] Thus, aldosterone promotes remodeling of organs and fibrosis independent of angiotensin II.

OTHER HORMONAL MEDIATORS

Endothelins

Several other regulatory hormones and cytokines have been identified as playing a role in the pathogenesis and adaptation to HF. The first of these are the endothelins.[24,25] Endothelin-1 (ET-1) is the most active. ET-1 is synthesized by vascular and airway smooth muscle, cardiomyocytes, leukocytes, and macrophages. Serum concentrations of ET-1 are elevated in HF, pulmonary HTN, MI, ischemia, and shock, and cause vasoconstriction, potentiation of cardiac remodeling, and decreased renal blood flow (RBF). Although the effects of ET-1 are detrimental in HF, its pharmacology is complex and dependent on the relative balance of two distinct G protein–coupled receptor subtypes referred to as ET_A and ET_B. As illustrated in Table 14-2, ET-1 can elicit opposing effects from each receptor, with the net effect being dependent on the relative density of the two receptors.

Possible future therapeutic agents could be specific inhibitors of one or more of the enzymes to prevent activation of ET-1. Alternatively, selective inhibitors of ET_A receptors could shift responses toward the favorable aspects of ET_B receptor activation. Bosentan and tezosentan are nonselective dual ET_A/ET_B antagonists. Bosentan has U.S. Food and Drug Administration (FDA) approval for the treatment of pulmonary HTN and is being investigated for use in HF.[8,9]

Natriuretic Peptides

Natriuretic peptides (NPs) are a family of peptides containing a common 17–amino acid ring. A-type natriuretic peptide, previously referred to as atrial natriuretic peptide or atrial natriuretic factor, is secreted by the atria in response to dilatation. Similarly, B-type natriuretic peptide (BNP) is produced by the ventricular myocardium in response to elevations of end-diastolic pressure and volume. Type-C natriuretic peptide (CNP) is secreted by lung, kidney, and vascular endothelium in response to shear stress. Collectively, the NPs are considered to be a favorable form of neurohormonal activation. Among their positive attributes are antagonism of the renin–angiotensin system, inhibition of sympathetic outflow, and ET-1 antagonism. The net effect is peripheral and coronary vasodilation decreasing preload and afterload. As their name implies, they also have diuretic or natriuretic properties, with improved RBF and glomerular filtration resulting from afferent arteriolar dilation and possibly efferent arteriolar constriction. Sodium reabsorption is blocked in the collecting duct due to indirect aldosterone inhibition. NPs also inhibit vasopressin secretion and block salt appetite and thirst centers in the CNS which contributes to diuresis. CNP has minimal diuretic properties.[26]

The BNP precursor is cleaved to produce the biologically active C-terminal fragment (BNP) and an inactive N-terminal fragment (NT-proBNP). Plasma level measurement of either BNP or NT-proBNP can be used as a biologic marker to differentiate HF-induced dyspnea from other causes of respiratory distress.[27–29] BNP levels less than 100 pg/mL usually indicate absence of HF, whereas levels greater than 400 pg/mL are highly indicative of HF. However, the interpretation of BNP levels between 100 and 400 pg/mL can be challenging because elevated levels are also associated with renal failure, pulmonary embolism, pulmonary HTN, and chronic hypoxia.[30] Higher concentrations correlate with the severity of HF. Clinical resolution of symptoms is often accompanied by a decline in BNP concentration.

Natriuretic hormone analogs or inhibitors of their metabolism have been investigated for drug therapy of HF. Nesiritide is a recombinantly produced human BNP approved by the FDA for IV management of acute HF exacerbations in hospitalized patients.[31,32] Downregulation of NP receptors, however, occurs during chronic HF, reducing the protective benefit of their actions and possibly limiting their usefulness as therapeutic entities.

Vasopressin Receptor Antagonists

Volume overload is associated with increased hospitalization. The potent vasoconstrictor ADH (arginine vasopressin) is inappropriately elevated in HF. Early studies with tolvaptan (selective vasopressin subtype V2 receptor antagonist) demonstrated improvement in congestive symptoms of HF and overall hemodynamic profile but no improvement in long-term outcome.[33]

Table 14-2

Biologic Effects of Endothelin-1

Organ System	ET_A Receptor Effects	ET_B Receptor Effects	Other Effects
Blood vessels	Potent vasoconstrictor	Vasodilation mediated through nitric oxide and prostacyclin release	
	Collagen deposition		
Heart	Hypertrophy and remodeling		↑ HR
			+/– inotropic effects
Lungs	Bronchoconstriction		
Kidney	Afferent and efferent vasoconstriction	Natriuresis and diuresis	
	Decrease in RBF and		

	GFR		
Neuroendocrine			Release of catecholamines, renin, aldosterone, and ANH

ANH, atrial natriuretic hormone; ET$_A$, endothelin A; ET$_B$, endothelin B; GFR, glomerular filtration rate; HR, heart rate; RBF, renal blood flow; +/–, positive/negative.
From Ergul A. Endothelin-1 and endothelin receptor antagonists as potential cardiovascular therapeutic agents. Pharmacotherapy. 2002;22:54.

The EVEREST trial studied the efficacy of vasopressin antagonism in HF.[34,35] Tolvaptan was evaluated in 4,133 patients with acute decompensated heart failure (ADHF) with NYHA class III or IV and LVEF of less than 40%. All patients also received standard therapy (ACE inhibitors [ACEIs], angiotensin receptor blockers [ARBs], β-blockers, diuretics, nitrates, and hydralazine). The patients were randomly assigned within 48 hours of hospitalization to 30 mg/day tolvaptan or placebo. The trial was a composite of three distinct analyses. The primary end point for the two identical short-term trials was to assess the change in global clinical status and body weight at day 7 or the day of discharge. The primary outcome for the long-term trial was all-cause mortality and cardiovascular (CV) death or HF hospitalizations. The results of the short-term trial showed modest improvement in the global clinical score compared with placebo. The main clinical benefit was change in body weight. The long-term trial failed to show any significant difference between the study drug and placebo in the primary end points. Common side effects of tolvaptan were dry mouth and thirst. In a small number of patients, hyponatremia was corrected. Because long-term mortality benefits are lacking and the cost of the drug is high, the use of tolvaptan is restricted to patients with hypervolemic hyponatremia associated with HF despite fluid restriction and diuretic use.

Calcium Sensitizers

Calcium sensitizers represent another class of drugs investigated for the treatment of ADHF. They exert positive inotropic effects by stabilizing the calcium–troponin C complex and facilitating actin–myosin cross-bridging without increasing myocardial consumption of adenosine triphosphate.[36] Levosimendan, the prototype for this drug class, has a dual mechanism of action to increase myocardial contractibility and induce vasodilation. Unlike other inotropic agents, it does not affect the intracellular calcium concentrations and, therefore, has a lower potential for proarrhythmia. The safety and efficacy of levosimendan in ADHF has been evaluated in placebo-controlled trials and in comparative trials with dobutamine. In patients with decompensated HF, levosimendan significantly reduced the incidence of worsening HF and improved hemodynamic indices.[37–39] In addition, mortality was lower in the levosimendan group. These trials, however, were not powered to show a difference in mortality as an end point. A subsequent trial comparing levosimendan with dobutamine in ADHF, designed to confirm the beneficial effects on morbidity and mortality, did not reduce all-cause mortality, which contrasts with earlier studies.[40] The most common adverse effects associated with levosimendan are headache and hypotension. Currently, levosimendan is approved in Europe for ADHF.

Inflammatory Cytokines, Interleukins, Tissue Necrosis Factor, Prostacyclin, and Nitric Oxide

Vascular endothelial cells release pro-inflammatory cytokines, vasodilator and vasoconstrictor substances, including interleukin cytokines (IL-1β, IL-2, IL-6), tumor necrosis factor (TNF-α), prostacyclin, and nitric oxide (NO; also known as endothelium-derived relaxing factor).[41–43] The role of these mediators in the pathogenesis of HF is unclear. Recent studies have shown that patients with HF have elevated levels of the pro-inflammatory cytokines IL-1β, IL-6, and TNF-α that correlate with the severity of disease.[43–45] Initial enthusiasm for use of the TNF-α receptor antagonist etanercept as a treatment for HF has been abandoned after disappointing results in trials.[46] At least 47 adverse event reports were made to the FDA describing new-onset HF or exacerbation of existing HF with etanercept and infliximab in patients being treated for either Crohn's disease or rheumatoid arthritis.[47]

Other investigators have tried using either NO or prostacyclin (epoprostenol) as vasodilators with mixed success.[48–50] There was a trend toward increased death rates with prostacyclin despite improved hemodynamic status during the Flolan International Randomized Survival Trial (FIRST).[50]

CARDIAC REMODELING

Progression of HF results in cardiac remodeling, characterized by changes in the shape and mass of the ventricles.[51] The three primary manifestations of cardiac remodeling are chamber dilatation, LV myocardial hypertrophy, and a resulting spherical shape of the LV (Fig. 14-3). Cardiac remodeling, which starts before the appearance of clinical symptoms, contributes to the progression of the disease.

Cardiac Dilatation

Cardiac dilatation results from hypervolemia. End-diastolic volume increases, myocardial fibers are stretched, and the ventricle(s) become dilated. In the healthy heart, the end-diastolic volume is 110 to 120 mL. With an EF of 60%, the SV would be 70 mL, leaving an end-systolic residual volume in the ventricle of 40 to 50 mL. With HFrEF, the end-diastolic volume increases resulting in an enlarged heart. Cardiac dilatation is less evident in HFpEF because normal contractility is maintained and the stiffened LV is resistant to filling and less likely to dilate (Fig. 14-3).

Frank–Starling Curve

The Frank–Starling curve (Fig. 14-4) demonstrates a curvilinear relationship between LV myocardial muscle fiber "stretch" (wall tension) and myocardial work. As stretch increases, the volume of blood ejected (SV) with each contraction increases. In systolic HF, the work capacity for any degree of stretch is diminished. A simple analogy is drawn using a balloon. The greater amount of air blown into a balloon, the more it stretches and, if released, the farther it flies around a room. As the balloon gets old, it loses its elasticity and thus has less recoil. Similarly, dilatation of the ventricles initially may serve as an effective compensating mechanism in systolic failure, but becomes inadequate as the elastic limits of the muscle fibers are reached. HR also increases to maintain CO when SV is low. The disadvantage of cardiac dilatation is increased myocardial oxygen demand. Theoretically, as cardiac dilatation progresses beyond a certain point, CO could decrease (as visualized on the descending limb of the Starling curve), but this is rarely observed clinically.

Cardiac Hypertrophy

Cardiac hypertrophy represents an absolute increase in myocardial muscle mass and muscle wall thickness (Fig. 14-3). This is analogous to increased skeletal muscle mass in response to weightlifting. Cardiac hypertrophy should not be confused with cardiac dilatation.

FUNCTIONAL LIMITATION CLASSIFICATION AND STAGES OF HEART FAILURE

New York Heart Association Classification

The NYHA classification scheme identifies four categories of functional disability associated with HF. Patients in class I are well compensated with no physical limitations and lack symptoms with ordinary physical activity. In class II, ordinary physical activity results in mild symptoms and imparts slight limitations on exercise tolerance. Patients in class III are comfortable only at rest; even less than ordinary physical activity leads to symptoms. In class IV, symptoms of HF are present at rest and no physical activity can be undertaken without symptoms. Determination of class is subjective and will vary among observers.

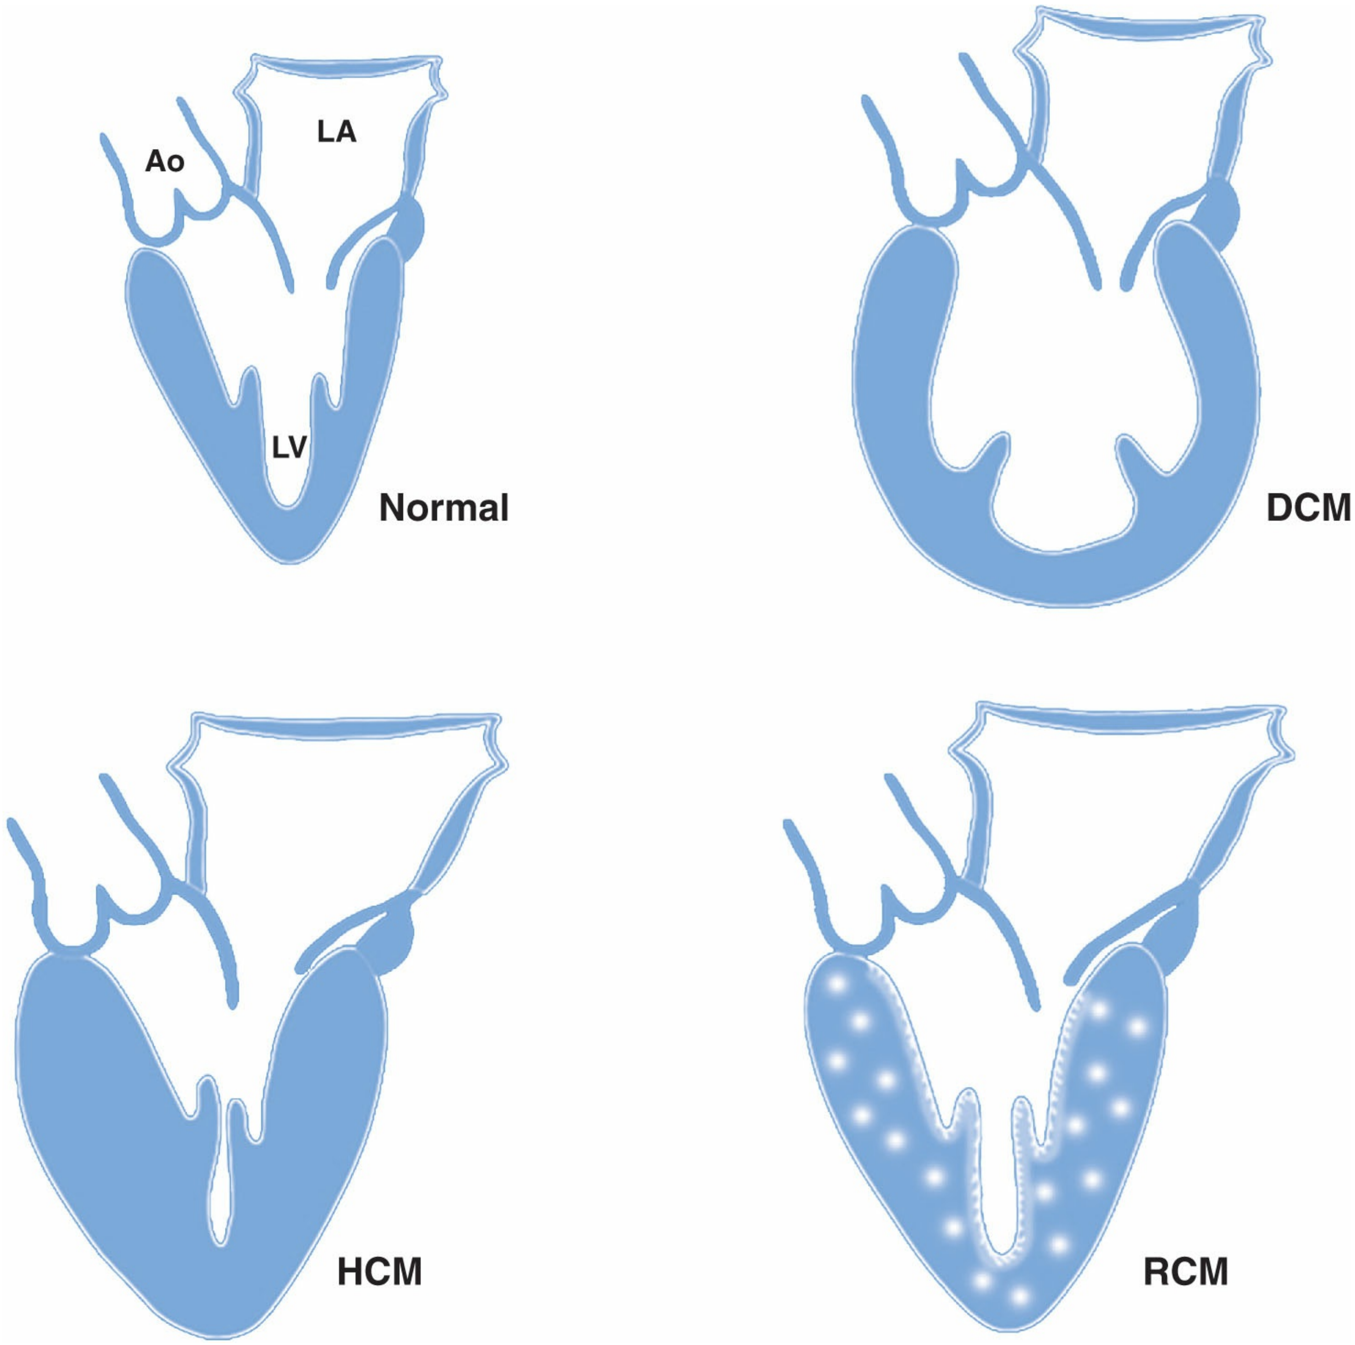

Figure 14-3 Cardiac remodeling. Dilated cardiomyopathy (DCM) results in thinning of the left ventricular walls and a decrease in systolic function; in hypertrophic cardiomyopathy (HCM), there is a marked thickening of the left ventricular walls leading to diastolic or systolic failure; and in restrictive cardiomyopathy (RCM), the left ventricular walls may be normal, hypertrophic, or slightly dilated, resulting in a decrease in diastolic compliance. Ao, aorta; LA, left articular; LV, left ventricular. (Adapted with permission from Topol EJ et al, eds. Textbook of Cardiovascular Medicine. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006.)

A shortcoming of the NYHA classification scheme is that it does not include asymptomatic individuals who are at high risk for developing HF and may benefit from preemptive lifestyle changes and drug therapy. The 2001 ACC/AHA guidelines introduced a new staging system that can be used in conjunction with the NYHA classifications.[4] Patients in stage A have HTN, CAD, diabetes mellitus, or other conditions that, if left untreated, can result in the development of overt HF. HF symptoms or identifiable abnormalities of the myocardium or heart valves are absent in stage A. Patients in stage B remain asymptomatic but have structural defects within the heart (LV hypertrophy, dilatation, low EF, or valvular disease). Patients in stage C exhibit varying degrees of HF along with structural changes in the heart. Stage D in the ACA/AHA scheme roughly correlates with NYHA class IV. Patients in this latter category are frequently hospitalized, and are considered to have end-stage disease. Figure 14-1 summarizes these two classification schemes and how they overlap. The most recent guidelines[1] expand the definition of HF and add two subgroups to the HFpEF category: those with borderline EF (LVEF 41%–49%), and those with improved EF (patients with previously reduced EF, but now with an LVEF >40%).

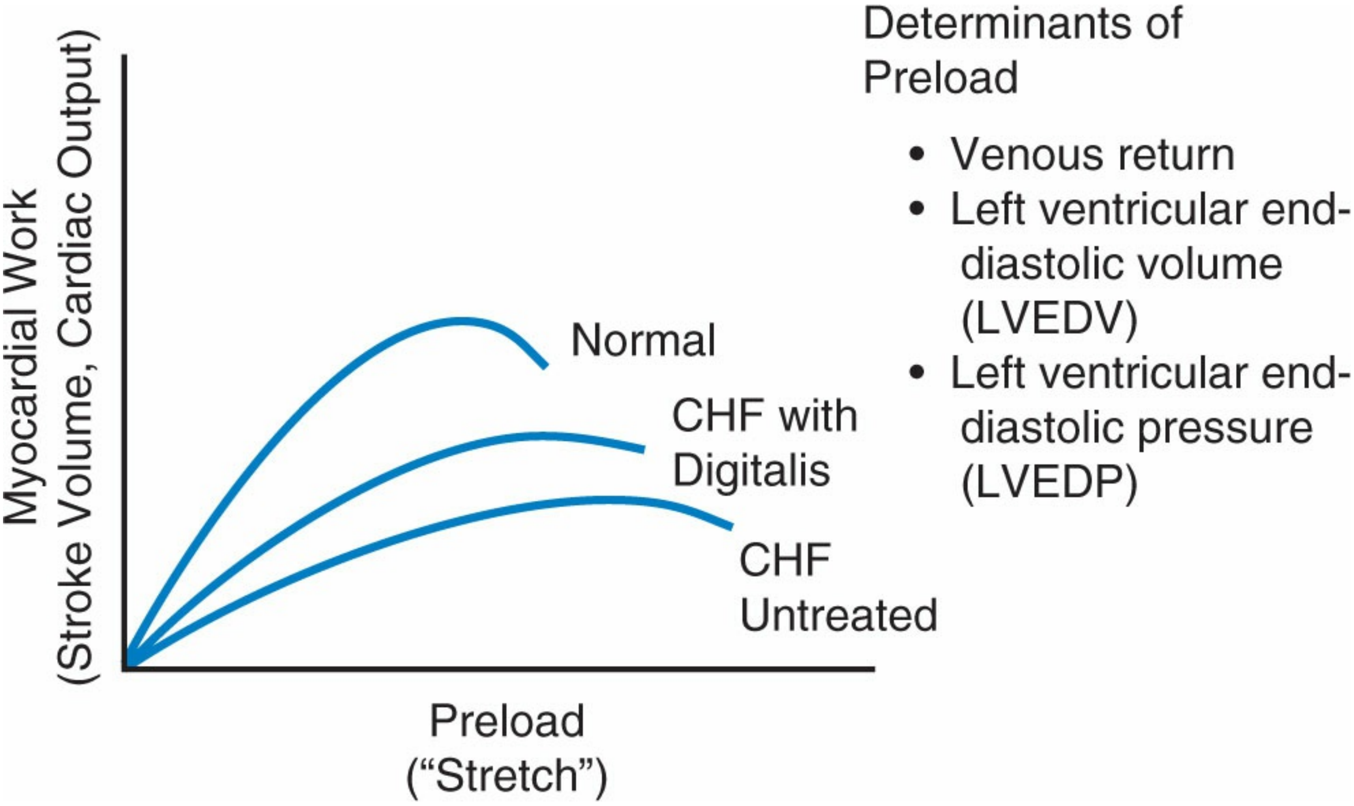

Figure 14-4 Representation of Frank–Starling ventricular function curve.

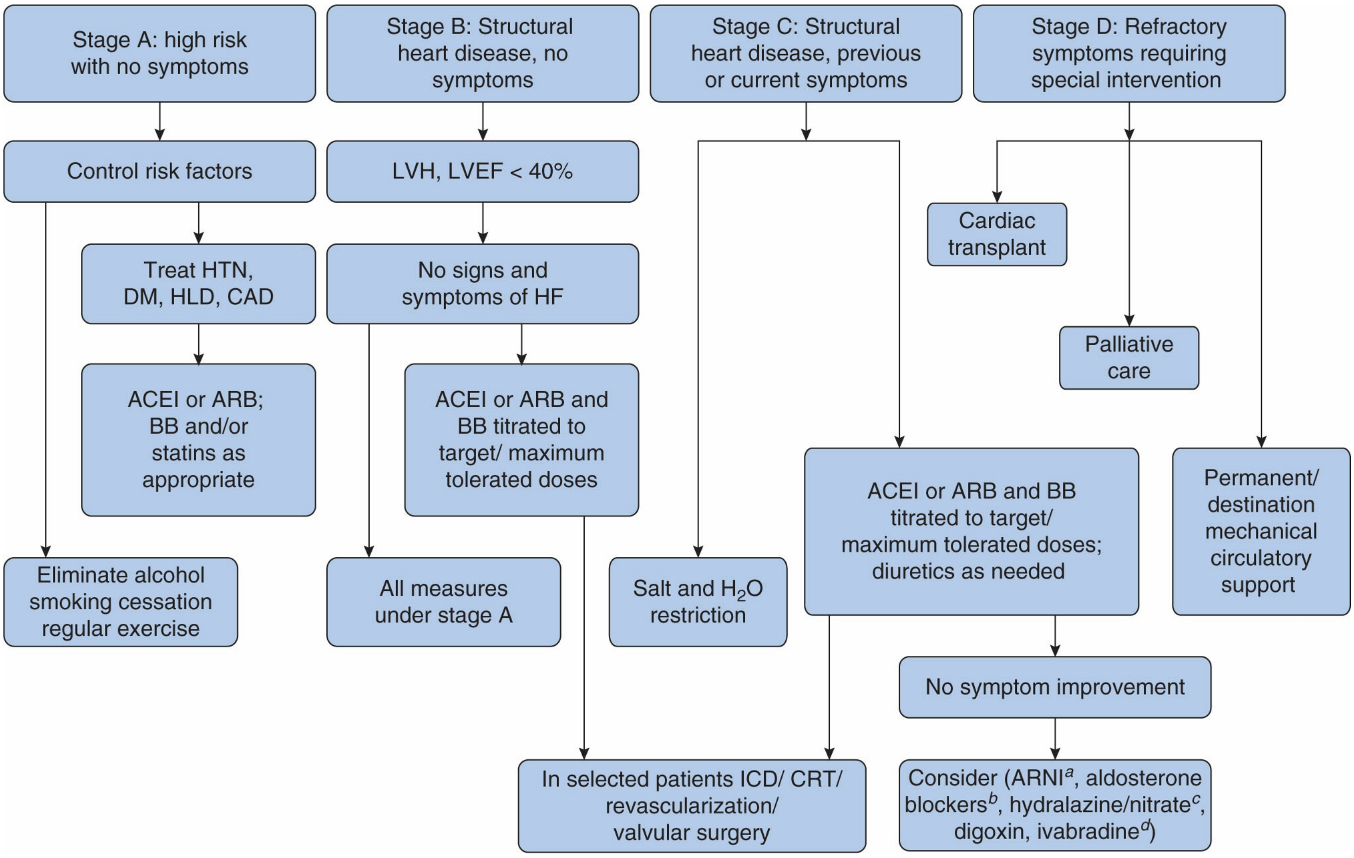
Overview of Treatment Principles

The ACC/AHA guidelines[1,5,6] updated their previous recommendations and expanded the role of both aldosterone antagonists and cardiac-resynchronization therapy (CRT) in patients with milder symptoms of HF. A clinical algorithm from the ACC/AHA guidelines is found in Figure 14-5.[1] The ACC/AHA Task Force recommends that most patients with HFrEF should routinely receive GDMT including an ACEI or an ARB, a β-adrenergic blocker, and an aldosterone receptor antagonist. Diuretics are recommended for patients with congestion. The combination of hydralazine and nitrate should be considered in in black patients with symptoms despite receiving other GDMT therapy or in patients unable to tolerate and ACEI or ARB. Digoxin is potentially beneficial in symptomatic patients with HFrEF already receiving optimal medical therapy to decrease HF hospitalizations.

The goals of therapy for HF are to abolish disabling symptoms, avoid complications such as arrhythmias, improve the quality of life, and prolong survival. Short of a heart transplant, none of the treatment measures are curative.

Nonspecific medical management of HF includes addressing CV risk factors, correcting underlying disease states (HTN, ischemic heart disease, arrhythmias, lipid disorders, anemia, or hyperthyroidism), performing moderate physical activity as tolerated, undergoing immunization with influenza and pneumococcal vaccines, and discontinuing possible drug-induced causes. The role of NPs, endothelin inhibitors, vasopressin receptor antagonists, and calcium sensitizers continues to be investigated. Non-digitalis inotropic agents and TNF-α inhibitors, although theoretically valuable, have yielded disappointing results and significant complications, including arrhythmias and increased mortality rates.



Stage A: high risk with no symptoms
Stage B: Structural heart disease, no symptoms
Stage C: Structural heart disease, previous or current symptoms
Stage D: Refractory symptoms requiring special intervention
Control risk factors
LVH, LVEF < 40%
Cardiac transplant
Treat HTN, DM, HLD, CAD
No signs and symptoms of HF
Palliative care
ACEI or ARB; BB and/or statins as appropriate
ACEI or ARB and BB titrated to target/ maximum tolerated doses
ACEI or ARB and BB titrated to target/ maximum tolerated doses; diuretics as needed
Permanent/ destination mechanical circulatory support
Eliminate alcohol smoking cessation regular exercise
All measures under stage A
Salt and H_2O restriction
No symptom improvement
In selected patients ICD/ CRT/ revascularization/ valvular surgery
Consider (ARNI[a], aldosterone blockers[b], hydralazine/nitrate[c], digoxin, ivabradine[d])

Figure 14-5 Stages in the development of heart failure and recommended therapy by stage. ACEI, angiotensin-converting enzyme inhibitors; ARB, angiotensin receptor blockers; BB, β-blockers; ARNI, angiotensin II receptor blocker neprilysin inhibitor; CAD, coronary artery disease; CrCl, creatinine clearance; DM, diabetes mellitus; EF, ejection fraction; HLD, hyperlipidemia; HTN, hypertension; ICD, implantable cardioverter-defibrillator; LVH, left ventricular hypertrophy.

[α] NYHA II or III who tolerate ACEI/ARB with adequate BP and no hx of angioedema – replace with ARNI to further reduce morbidity and mortality, must wait at least 36 hours of the last dose of ACEI

[β] NYHA II-IV unless est. CrCl < 30 mL/min and serum potassium > 5.0 mEq/L

[c] NYHA III or IV in black patients

[d] NYHA II or III, LVEF ≤35%, maximally tolerated dose of beta blocker, sinus rhythm, heart rate 70 bpm or

greater

Treatment of HFpEF is less well defined.[12,52–54] A sodium-restricted diet and diuretics are indicated for symptomatic relief of SOB or edema. Because these patients typically present with comorbid conditions (atrial fibrillation [AF], HTN, diabetes mellitus, and CAD), treatment of comorbidities with available therapies should aim to decrease CV events and improve survival.

PHYSICAL ACTIVITY

Patients should be encouraged to exercise to maintain physical conditioning. Treatment goals include prolonging life and improving quality of life. The results of The Effects of Exercise Training on Health Status in Patients with Chronic Heart Failure (HF-ACTION)[55] trial showed that a highly structured exercise program in HF patients did not reduce all-cause mortality or all-cause hospitalization when compared with patients who were getting the usual care in which exercise was simply encouraged. However, according to the HF-ACTION substudy, the structured exercise training program improved the overall Kansas City Cardiomyopathy Questionnaire (KCCQ) score (a test that includes questions on physical limitations, symptoms, quality of life, and social limitations). The improvement occurred early on and was sustained for 3 years. The ACC/AHA HF guidelines[1,5,6] recommend exercise training as safe and effective for patients with HF who are able to participate in symptom control.[1,5,6] However, during acute exacerbations, bed rest and restricted physical activity decrease the metabolic demands, and minimize gravitational forces contributing to edema. Renal perfusion is increased in the prone position, resulting in diuresis and mobilization of fluid.

SODIUM-RESTRICTED DIET

Dietary indiscretion (high salt intake) is often cited as the cause of HF exacerbations and hospital admissions. Several observational studies have demonstrated associations between lower dietary sodium intake and reduced hospitalizations and mortality.[56,57] In contrast, several randomized trials imply that dietary sodium restriction in patients with CV diseases may be deleterious. One of the largest meta-analysis in patients with HFrEF showed that compared with control groups (2,800 mg/day), the sodium-restricted groups (1,800 mg/day) had increased morbidity and mortality.[58] The trials included in this analysis had several limitations. High doses of diuretics were used in conjunction with strict fluid restriction, which could have resulted in intravascular volume depletion and adverse outcomes. Also, many patients were not on optimal doses of GDMT. There is limited evidence to support sodium restriction in the inpatient setting. In one trial, sodium restriction greater than the standard 2,000 mg/day in hospitalized HFrEF patients did not affect clinical stability or decrease length of stay.[59] For these reasons, further randomized trials are needed to elucidate the impact of sodium restriction on outcomes in HF patients.

Because high sodium intake leads to HTN, LV hypertrophy, and CV disease, the ACC/AHA HF guidelines[1,5,6] recommend 1.5 g/daily sodium restriction for patients with stage A and B HF. In patients with advanced HF (stages C and D), <3 g/daily is recommended due to lack of sufficient data to support any specific degree of restriction.

Table 14-3

Loop Diuretic Dosing[1]

	Furosemide	**Bumetanide**	**Torsemide**
IV loading doses	40 mg	1 mg	20 mg
Maximum total daily dose	600 mg	10 mg	200 mg
Ceiling dose			
Normal renal function	80–160 mg (PO/IV)	1–2 mg (PO/IV)	20–40 mg (PO/IV)
Cl_{cr}: 20–50 mL/minute	160 mg (PO/IV)	2 mg (PO/IV)	40 mg (PO/IV)
Cl_{Cr}: <20 mL/minute	200 mg (IV), 400 mg (PO)	8–10 mg (PO/IV)	100 mg (PO/IV)
Bioavailability	10%–100%	80%–90%	80%–100%
Duration of action	6–8 hours	4–6 hours	12–16 hours

Cl_{Cr}, creatinine clearance; IV, intravenous; PO, oral.

Even though adherence to dietary sodium restriction is considered “a cornerstone of HF disease management,” there are many challenges in implementing dietary sodium restriction. Barriers such as lack of knowledge, interference with socialization, limited access to appropriate food selections, and increased taste preference for salty foods all contribute to lack of adherence to low sodium diet.[60,61] Although less than 1 g of sodium chloride (NaCl) is required to meet physiologic needs, the average U.S. diet contains 10 g. Dietary sodium can be reduced to 2 to 4 g of NaCl by eliminating cooking salt. This diet is more palatable and leads to better adherence than a severely salt-restricted diet.

DIURETICS

Only those points salient to the treatment of HF are included in this chapter. Diuretic use is discussed in Chapter 9, Essential Hypertension and Chapter 27, Fluid and Electrolyte Disorders.

Diuretics are indicated in HF patients with congestion (pulmonary and/or peripheral edema). They produce rapid symptomatic relief. Because activation of the RAAS and sympathetic nervous system contributes to the progression of HF, diuretics should be combined with an ACEI and a β-blocker unless contraindications exist.[1]

Initially, the goal of diuretic therapy is symptomatic relief of HF by decreasing excess volume without causing intravascular volume depletion. Once excess volume is removed, therapy is aimed at maintaining sodium balance and preventing accumulation of new fluid, while avoiding dehydration. The rate at which volume can be removed is limited by its rate of mobilization from the interstitial to the intravascular fluid compartment. If diuresis is too vigorous, intravascular volume depletion, hypotension, and a paradoxical decrease in CO may result. Diuretic doses are titrated so that urine output increases and weight decreases, generally by 0.5 to 1.0 kg daily.[1]

The effectiveness of diuretics depends on the amount of sodium delivered to their site of action and the patient's renal function.[62,63] Proximal tubular reabsorption of sodium is increased in patients with severe HF when RBF is compromised, rendering thiazide and potassium-sparing diuretics (which act primarily on the distal tubule) minimally effective. Thiazides are believed to lose their effectiveness when creatinine clearance decreases to less than 30 mL/minute. Metolazone is an exception in that its activity may be preserved in these patients. The loop diuretics (furosemide, bumetanide, and torsemide) are more potent than thiazides, and retain their effectiveness in renal insufficiency. Thus, in most patients with HF, loop diuretics are preferred. In addition to having activity in the ascending limb of the loop of Henle, furosemide has vasodilating properties that decrease renal vascular resistance. The usual recommended doses for the loop diuretics are found in Table 14-3.[62]

The effectiveness of diuretics depends on active secretion of the drug in the proximal tubule. Slow absorption (even if bioavailability is high) or protein binding impairs tubular delivery and compromises diuretic response. Once the drug is in the tubule and the threshold for diuresis is met, further drug delivery produces no greater diuresis. Increasing single doses beyond the ceiling dose produces no additional diuretic response; however, improved diuresis may be obtained by giving the drug more frequently.

A combination of diuretics (a loop diuretic and thiazide) is used in patients who are refractory to high-dose loop diuretics.[62,63] Despite their effects on reducing HF symptoms, loop diuretics do not counteract the underlying cause of HF or modify mortality rates.

ALDOSTERONE ANTAGONISTS

The aldosterone antagonists eplerenone and spironolactone exert a mild diuretic effect by competitive binding to the aldosterone receptor site in the distal convoluted renal tubules. The Randomized Aldactone Evaluation Study (RALES) investigators found that spironolactone reduced both morbidity and mortality in patients in NYHA class III and IV.[64] The authors speculated that the beneficial effect of spironolactone was related to a reduction in aldosterone-induced vascular damage and myocardial or vascular fibrosis rather than its diuretic effect. Similarly, reduced mortality was observed in patients with LV dysfunction after a recent MI who were treated with eplerenone.[65] The ACC/AHA HF guidelines[1,5,6] recommend the addition of an aldosterone antagonist in all patients with HFrEF who are already on ACEIs (or ARB) and β-blockers irrespective of the severity of symptoms and in patients immediately after MI who have LV dysfunction or diabetes.[65] On initiating aldosterone receptor antagonists, GFR should be>30 mL/minute/1.73 m^2 and potassium levels <5 mEq/dL to avoid the risk of hyperkalemia or renal insufficiency.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS AND ANGIOTENSIN RECEPTOR BLOCKERS

Drugs with vasodilating properties are a primary treatment for HF. Arterial dilation provides symptomatic relief of HF by decreasing arterial impedance (afterload). Venous dilation decreases LV congestion (preload). The combination of these two properties provides additive benefits to alleviate the symptoms of HF and increase exercise tolerance. The first vasodilator drugs to be studied were hydralazine (an arterial dilator) and nitrates (predominately venous dilators). By combining these two drugs, significant reductions in HF symptoms can be achieved along with a reduction in mortality rates. With the advent of ACEIs, the use of hydralazine and nitrates has been relegated to a secondary role.

ACEIs possess both afterload- and preload-reducing properties and volume-reducing potential. They produce similar hemodynamic effects to the hydralazine–nitrate combination as a single agent, favorably modify cardiac remodeling, and have a more tolerable side effect profile. These advantages led to the recommendations that ACEIs are the drugs of choice for initial therapy, even in patients with relatively mild LV systolic dysfunction.[1]

The ACC/AHA guidelines[1,5,6] state that ACEIs should be prescribed to all patients with HFrEF unless they have a contradiction to their use or are unable to tolerate these drugs. In general, ACEIs are used with β-blockers. ACEIs should be initiated at low doses, and titrated to target doses if well tolerated. Fluid retention can blunt the therapeutic effects, and volume depletion can potentiate the adverse effects of ACEIs. Clinicians should attempt to use doses that have been shown to reduce CV events in clinical trials, but they should not delay the initiation of β-blockers in patients because of a failure to reach target ACEI doses.[1]

The pharmacologic actions of all the ACEIs are essentially identical, but some of them have not been studied or received FDA approval for use in HF (Table14-4). Their value in HFpEF still is unclear. A related class of drugs is the ARBs.[66,67] ARBs offer theoretic advantages compared with ACEIs by being more specific for angiotensin II blockade (preferentially bind to AT_1 receptors) and having a lower risk of drug-induced cough.

ARBs can be used as alternatives to ACEIs in patients who are intolerant (angioedema or cough). Triple combination of an ACEI, ARB, and an aldosterone receptor antagonist is potentially harmful for patients and therefore is listed as a class III (avoid) recommendation in the ACC/AHA guidelines.[1,5,6] Currently, only candesartan and valsartan are FDA-approved for the treatment of HF.

β-ADRENERGIC BLOCKING AGENTS

Until the mid-1990s, β-blockers were contraindicated in patients with HFrEF. This was based on the belief that sympathomimetic agonists and other positive inotropic drugs were the logical choices to counteract systolic failure and that negative inotropic drugs would exacerbate HF. A better understanding of the pathophysiology of HF led to a rethinking of this logic.[15–20,22] In combination with ACEIs, β-blockers are considered first-line agents in patients with HFrEF. The ACC/AHA guidelines state that β-blockers should be prescribed to all patients with HFrEF unless they have a contraindication to their use or are unable to tolerate the treatment. Intolerance or resistance to other HF therapies should not preclude or delay the initiation of β-blocker use in patients with HFrEF.[1] Although some patients can have a temporary worsening of symptoms, continued use results in improved quality of life, fewer hospitalizations, and most importantly, a reduction in mortality by approximately 34% when added to other HF therapies. Extended-release metoprolol succinate, carvedilol, and bisoprolol are FDA approved for use in HFrEF. Metoprolol and bisoprolol are both partially selective β_1-blockers, and carvedilol is a mixed α_1- and nonselective β-blocking agent.

DIGITALIS GLYCOSIDES (DIGOXIN)

Digoxin has several pharmacologic actions on the heart. It binds to and inhibits sodium-potassium (Na^+/K^+) adenosine triphosphatase (ATPase) in cardiac cells, decreasing outward transport of sodium and increasing intracellular concentrations of calcium within the cells. Calcium binding to the sarcoplasmic reticulum causes an increase in the contractile state of the heart.

At one time, the primary benefit of digoxin in HFrEF was assumed to be an increase in the force of contraction (positive inotropic effect). We now know that digoxin has beneficial neurohumoral and autonomic effects caused by reducing sympathetic tone and stimulating parasympathetic responses at serum concentrations below those associated with positive inotropism.[68,69] Inhibition of Na^+/K^+ ATPase in vagal afferent fibers sensitizes cardiac baroreceptors, resulting in reduced sympathetic outflow from the CNS. Similarly, inhibition of Na^+/K^+ ATPase in renal cells reduces renal tubular reabsorption of sodium and indirectly suppresses renin secretion. This has led to the suggestion that the positive benefits of digoxin can be obtained by using small doses.

Digoxin decreases the conduction velocity and prolongs the refractory period of the atrioventricular (AV) node. This AV node–blocking effect prolongs the PR interval and is the basis for use of digoxin in slowing the ventricular response rate in patients with AF and other supraventricular arrhythmias (see Chapter 15, Cardiac Arrhythmias).

Several studies have confirmed a clinical benefit for digoxin in reducing HF symptoms, independent of rhythm status, but there are no data that demonstrate a beneficial effect on survival. Digoxin is used for symptom management in patients optimally treated with ACEIs, β-blockers, and aldosterone antagonists. In symptomatic patients in stage C or stage D, digoxin can reduce HF-related hospitalizations.[1] Digoxin can also be considered in patients with HF who also have AF, although β-blockers are more effective than digoxin in controlling the ventricular response, especially during exercise.

OTHER VASODILATING DRUGS: HYDRALAZINE AND NITRATES

Although ACEIs are drugs of choice, the first vasodilators evaluated in HFrEF were hydralazine and nitrates. Hydralazine provides symptomatic relief of HF by decreasing afterload. Nitrates have venous dilating properties that decrease preload. Used in combination, these two agents have additive benefits in alleviating the symptoms of HF and increasing exercise tolerance. Importantly, the hydralazine–isosorbide dinitrate combination was the first treatment regimen to show improved survival in severe HF compared with placebo[70] (while patients continued their diuretic or digitalis therapy). The African American Heart Failure Trial (AHeFT)[71] showed that the addition of hydralazine combined with isosorbide dinitrate to standard HF therapy with an ACEI or a β-blocker improved survival and reduced HF hospitalizations. Based on the results of AHeFT, the FDA approved the combination product of hydralazine and isosorbide dinitrate (BiDil) for the treatment of HFrEF as an adjunct to standard HF therapy in African American patients. The combination of hydralazine and nitrate is reasonable in patients with current or prior HF symptoms and reduced LVEF who cannot tolerate ACEIs or ARBs, and is also recommended for patients self-described as African American with moderate to severe symptoms on optimal therapy with ACEIs, β-blockers, and diuretics.[1] IV NTG and nitroprusside (a mixed arterial and venous dilator) are also used in hospitalized patients with acute HF exacerbations. The role of these vasodilators in HFpEF is not well studied.

OTHER INOTROPIC AGENTS

IV dopamine and dobutamine, which are sympathomimetics, and milrinone (phosphodiesterase inhibitor) are used in acutely decompensated HF (see Chapter 17, Shock). They are associated with an increased incidence of mortality but frequently used short term for ADHF. Both dobutamine and milrinone are used chronically in some stage D patients.

Initial positive hemodynamic effects during the first few weeks to months of therapy are followed by increased mortality with continued therapy when compared with placebo. This is related to proarrhythmic effects. Inotropic drugs are contraindicated in HFpEF.

CALCIUM-CHANNEL BLOCKERS

Amlodipine, felodipine, isradipine, nifedipine, and nicardipine are examples of dihydropyridine calcium-channel blockers with arterial vasodilating effects. Compared with the nondihydropyridine calcium-channel blockers (verapamil and diltiazem), they have minimal negative inotropic properties. Only amlodipine[72] and felodipine[73] have been documented to be safe in HF, but only a small subset of patients with nonischemic dilated cardiomyopathy actually had a beneficial effect of improved survival with amlodipine.[72] Verapamil and diltiazem are safe to use in HFpEF and may improve symptoms by reducing HR and allowing more time to fill the ventricle, but should be avoided in patients with HFrEF due to their negative inotropic effects.

IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR

Ventricular arrhythmias are common in patients with HF ranging from asymptomatic ventricular premature beats to sustained ventricular tachycardia, ventricular fibrillation, and sudden cardiac death (SCD). SCD is highest in patients with severe HF symptoms, or stage D HF.[1] Patients with previous cardiac arrest or documented sustained ventricular arrhythmias have a higher risk of future events. An implantable cardioverter-defibrillator (ICD) implantation is indicated for secondary prevention of SCD in HF patients who have good clinical function and prognosis and low EF and experience syncope of unknown origin, as well as in a small subset of HF patients who are awaiting a planned cardiac transplant. The ACC/AHA guidelines[1] also recommend ICD for primary prevention of SCD in patients with nonischemic dilated cardiomyopathy or ischemic heart disease at least 40 days after MI, EF of 35% or less despite optimal drug therapy, with mild to moderate symptoms of HF and in whom survival with good functional capacity is otherwise anticipated to extend beyond 1 year (see Case 14-5, Question 4, for detailed discussion).

CARDIAC RESYNCHRONIZATION

CRT is a therapeutic approach for treating patients with ventricular dyssynchrony (defined as a QRS duration of at least 120 ms). Selected HF patients benefit from simultaneous pacing of both ventricles (biventricular pacing), or of one ventricle in patients with bundle branch block. The rationale for using CRT is that dyssynchrony causes ventricular remodeling and worsens HF. CRT can be used alone or with an

ICD device. Several clinical trials with CRT or CRT-D[74–77] (cardiac resynchronization defibrillator therapy) have demonstrated improvements in HF functional status, survival, and reduction in hospitalizations. The approved indication for cardiac CRT-D includes patients with NYHA class II or ischemic class I HF, with an EF of less than 30% and a QRS duration of longer than 130 ms, and left bundle branch block. These indications are based on results[75] which showed a significant reduction in HF events among patients with mild HF symptoms with CRT-D compared with ICD alone. Current guidelines[1] support the use of CRT in patients with NYHA class II, III or ambulatory IV symptoms on GDMT, LVEF of 35% or less, and LBBB with a QRS ≥150 ms (see Case 14-6, Questions 1 and 2).

LEFT VENTRICULAR ASSIST DEVICES

A left ventricular assist device (LVAD) is a battery-operated, mechanical pump that is surgically implanted to maintain the pumping ability of the heart. Clinical trials using LVADs have shown improvement in survival and quality of life. For patients with end-stage HF, LVADs are used as a bridge to transplant or as destination therapy, which is permanent device implantation for patients who are not candidates for a transplant.

The landmark trial REMATCH[78] (Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure) found that end-stage HF patients who received an LVAD (HeartMate XVE) had a 52.1% chance of surviving 1 year, compared with a 24.7% survival rate for patients who received optimal medical therapy. At 2 years, the survival was 23% for the LVAD patients versus 8% for those receiving medical therapies. However, these survival rates were much lower than those seen with transplantation. Advances in technology led to the introduction of the second-generation devices, notably HeartMate II, which was approved as a bridge to transplant in 2008.[79] In January 2010, the HeartMate II (continuous flow), a smaller device, was approved for destination therapy. In a head-to-head comparison with the first-generation HeartMate XVE (pulsatile flow), 1- and 2-year survival rates were 68% and 58% with HeartMate II versus 55% and 24% with HeartMate XVE.[80] Adverse events were less frequent with the continuous-flow device and patients reported significant improvements in their quality of life. Recently, a new novel pump called HeartWare left ventricular assist device (HVAD) was tested in patients awaiting cardiac transplantation with refractory and advanced HF. This device is small and can be directly implanted into the pericardial sac. The nonrandomized ADVANCE trial[81] (Evaluation of the HVAD for the Treatment of Advanced Heart Failure) enrolled 140 patients who received HVAD compared with 499 patients who received an LVAD. The primary end points were survival and success rates at 180 and 360 days after implantation. At 180 days the survival was 92.0% for the HVAD group and 90.1% for the control group ($p < 0.001$). There was less bleeding and fewer infections reported with HVAD; however, the incidence of stroke was higher. New clinical trials are being designed and conducted to evaluate adverse events between HVAD and HeartMate II. Until further improvements are implemented and demonstrated, cardiac transplantation remains the gold standard for the treatment of end-stage HF.

NEW THERAPIES IN HFREF

Ivabradine

There is considerable evidence of an association between elevated HRs (HRs >80 beats/minute [bpm]) and increased risk of mortality in patients with HF. The HF trials with β-blockers demonstrated increased mortality with elevated baseline resting heart rates (RHR) >90 bpm.[82,83] Post hoc analysis of CHARM[84] showed that increased RHR was an independent predictor of mortality regardless of LV function or use of β-blockers. A subsequent meta-analysis of HF trials[85] showed an association between the magnitude of HR reduction and survival benefit.

Ivabradine is a selective I_f ("funny current") inhibitor which lowers HR by acting on the sinoatrial node. In 2010, the Systolic Heart Failure Treatment With the I_f Inhibitor Ivabradine Trial (SHIFT)[86] provided evidence for the benefit of HR lowering in patients with HF. SHIFT randomized 6,558 patients with symptomatic HF to ivabradine versus placebo. Patients had an EF ≤35%, normal sinus rhythm with a HR of ≥70 bpm, and at least one hospitalization for HF within the previous year. In addition to background treatment, which generally included a β-blocker, patients received either ivabradine to maintain a RHR between 50 and 60 bpm, or placebo. During a median 23 months of follow-up, patients in the ivabradine group had an 18% decrease in risk for CV death or hospitalization (hazard ratio, 0.82; $p < 0.0001$). Ivabradine significantly reduced the risk of hospitalization for worsening HF and death due to HF, but did not have a significant effect on all-cause mortality. Ivabradine was well tolerated with relatively few adverse events, although significantly more than placebo. The most common adverse events were bradycardia and visual disturbances.

In April 2015, the FDA approved ivabradine (Corlanor) for symptomatic chronic HF with LVEF ≤35%, to reduce the risk of hospitalization for worsening HF in adults. Because ivabradine did not reduce all-cause mortality, its broader application in clinical practice will emerge as more evidence becomes available.The 2016 ACC/AHA/HFSA update on 2013 HF guidelines notes that ivabradine can be beneficial to reduce HF hospitalization for patients with symptomatic (NYHA class II–III) stable chronic HFrEF (≤35%) who are receiving maximal GDMT, including a β-blocker at maximum tolerated dose, and in sinus rhythm with a heart rate of greater than or equal to 70 bpm at rest. It received a class IIa recommendation, level of evidence B-R.[5]

ANGIOTENSIN RECEPTOR-NEPRILYSIN INHIBITOR

The NP hormones are responsible for both natriuresis and diuresis and are broken down by the neutral endopeptidase neprilysin, which also degrades angiotensin II. Several neprilysin inhibitors (ecadotril, candoxatril, omapatrilat) have been developed to target this pathway in order to increase concentrations of NPs. Unfortunately, lack of efficacy and side effects led to discontinuation of their development. A new drug sacubitril/valsartan (Entresto) has shown improved outcomes with few adverse effects in patients with HFrEF. Sacubitril/valsartan is an angiotensin receptor-neprilysin inhibitor (ARNI), a unique combination with an ARB (valsartan) and a neprilysin inhibitor (sacubitril). Because neprilysin also breakdowns angiotensin II, a neprilysin inhibitor should be given in combination with a RAAS inhibitor. Sacubitril/valsartan provides a dual mechanism of action in HF by inhibiting the renin–angiotensin–aldosterone axis and augmenting several endogenous NPs. This mechanism has not been addressed by other HF therapies.

This was tested in a randomized, double-blind trial "**P**rospective comparison of **A**ngiotensin **R**eceptor neprilysin inhibitors with **A**ngiotensin converting enzyme inhibitors to **D**etermine **I**mpact on **G**lobal **M**ortality and Morbidity in **H**eart **F**ailure" (PARADIGM-HF)[83] that compared sacubitril/valsartan (400 mg daily) to enalapril (20 mg daily) in patients with a LVEF <35% and elevated BNP levels, almost all of whom were in NYHA class 2 to 3. At baseline, most patients in both groups were receiving the recommended pharmacologic treatment for HFrEF. At 3.5 years of follow-up, there was a significant reduction in the primary outcome of CV death or HF hospitalization in the sacubitril/valsartan group (21.8%) versus the enalapril group (26.5%). Patients receiving sacubitril/valsartan had lower rates of hyperkalemia, renal dysfunction, and cough, but higher rates of hypotension. Fewer patients in the sacubitril/valsartan group required treatment intensification and use of advanced therapies (inotropes, assist devices, cardiac transplantation) when compared with enalapril.

ACEIs have had a class I recommendation based on their magnitude of CV mortality prevention (18%) in HF. The finding that sacubitril/valsartan has a superior effect on CV mortality compared to enalapril lends support that an ARNI could replace ACEI and ARBs in patients with HFrEF who remain symptomatic despite being on optimal GDTM. However, it should be noted that fewer patients in both groups had CRT or ICD therapy compared to contemporary treatment in the United States. This is the first study which used substitution of an ACEI rather than an add-on strategy in chronic HF. Even though the ARNI clearly met the criteria for clinical superiority when compared with conventional therapy, the benefits have to be weighed against the side effect profile. In clinical practice, the frequency of the side effects (hypotension, angioedema) may be more pronounced due to a more complicated patient population. The drug was approved by FDA in 2015 for NYHA class I–IV. Post-marketing surveillance will determine the safety of sacubitril/valsartan. A cost–benefit analysis would also be of use.

The 2016 ACC/AHA/HFSA update on 2013 HF guidelines recommends an ARNI in patients with chronic symptomatic HFrEF (NYHA class II or III) who tolerate an ACE inhibitor or ARB, in order to further reduce morbidity and mortality. It has a class I, level of evidence B-R recommendation.[5] The guidelines also state that ARNI should not be combined with ACE inhibitors and a 36-hour washout period is required between these two therapies to minimize the risk of angioedema.

Given the positive results of the Paradigm trial, the benefit of sacubitril/valsartan in HFpEF patients is being evaluated in an ongoing study: “Efficacy and Safety of LCZ696 Compared to Valsartan, on Morbidity and Mortality in Heart Failure Patients With Preserved Ejection Fraction (PARAGON–HF).”[88] The primary end point is to determine whether sacubitril/valsartan can reduce CV death or total HF hospitalizations in patients with HFpEF.

PATIENT EVALUATION

Signs and Symptoms

CASE 14-1

QUESTION 1: A.J., a 58-year-old man, is admitted with a chief complaint of increasing SOB and an 8-kg weight gain. Two weeks before admission, he noted the onset of dyspnea on exertion (DOE) after one flight of stairs, orthopnea, and ankle edema. Since then, his symptoms have worsened. He has also noted episodic bouts of paroxysmal nocturnal dyspnea (PND), and he has been able to sleep only in a sitting position. A.J. reports a productive cough, nocturia (two to three times a night), and edema.

A.J.’s other medical problems include a long history of heartburn, a 10-year history of osteoarthritis, depression, and poorly controlled HTN. A family history of diabetes mellitus is also present.

Physical examination reveals dyspnea, cyanosis, and tachycardia. A.J. has the following vital signs: BP, 160/100 mm Hg; pulse, 90 bpm; and respiratory rate, 28 breaths/minute. He is 5 feet 11 inches tall and weighs 78 kg. His neck veins are distended. On cardiac examination, an S_3 gallop is heard; the point of maximal impulse is at the sixth intercostal space, 12 cm from the midsternal line. His liver is enlarged and tender to palpation, and a positive hepatojugular reflux is observed. He is noted to have 3+ pitting edema of the extremities and sacral edema. Chest examination reveals inspiratory rales and rhonchi bilaterally.

The medication history reveals the following current medications: hydrochlorothiazide (HCTZ) 25 mg every day, ibuprofen 600 mg 4 times a day (QID), ranitidine 150 mg every night at bedtime, and citalopram 20 mg every day. He has no allergies and no dietary restrictions.

Admitting laboratory values include the following:

Hematocrit	41.1%
White blood cell count	5,300/μL
Sodium (Na)	132 mEq/L
Potassium (K)	3.2 mEq/L
Chloride (Cl)	100 mEq/L
Bicarbonate	30 mEq/L
Magnesium	1.5 mEq/L
Fasting blood sugar	100 mg/dL
Uric acid	8 mg/dL
Blood urea nitrogen (BUN)	40 mg/dL
Serum creatinine (SCr)	0.8 mg/dL
Alkaline phosphatase	44 units/L

Aspartate aminotransferase, 30 units/L
BNP, 1,364 pg/mL (normal <100 pg/mL)
Thyroid-stimulating hormone, 2.0 microunits/mL

The chest radiograph shows bilateral pleural effusions and cardiomegaly. What signs, symptoms, and laboratory abnormalities of HF does A.J. exhibit? Relate these clinical findings to the pathogenesis of the disease and to left-sided or right-sided HF.

Left-sided ventricular dysfunction primarily causes pulmonary symptoms, whereas right-sided ventricular dysfunction causes signs of systemic venous congestion. Although LV failure usually develops first, many patients present with signs of biventricular failure. The signs and symptoms of both left-sided and right-sided ventricular dysfunction are summarized in Table 14-4.

LEFT-SIDED HEART FAILURE (LEFT VENTRICULAR DYSFUNCTION)

Weakness, fatigue, and cyanosis result from decreased CO and compromised tissue perfusion. If the LV is not emptied completely, pulmonary congestion occurs. Dyspnea (labored or uncomfortable breathing) on exertion, a productive cough, rales (crackles in the lung during auscultation), pleural effusions on chest radiograph, and hypoxemia all result from pulmonary congestion. Pulmonary symptoms are aggravated in the reclining position. Orthopnea or SOB in the supine position is quantified by the number of pillows the patient must lie on to sleep comfortably. A.J., for example, could sleep only sitting upright. PND is characterized by SOB that awakens the patient from sleep and is alleviated by an upright position.

Table 14-4

Signs and Symptoms of Heart Failure

Left Ventricular Failure	Right Ventricular Failure[a]
Subjective	
DOE	
SOB	
Orthopnea (2–3 pillows)	
PND, cough	
Weakness, fatigue, confusion	Peripheral edema
Weakness, fatigue	
Objective	
LVH	Weight gain (fluid retention)
↓BP	
EF <40%[b]	Neck vein distension
RALES, S_3 gallop rhythm	Hepatomegaly

Reflex tachycardia	Hepatojugular reflux
↑BUN (poor renal perfusion)	

[a] Isolated right-sided failure occurs with long-standing pulmonary disease (cor pulmonale) or after pulmonary hypertension.

[b] Ejection fraction normal in patients with diastolic dysfunction.

BP, blood pressure; BUN, blood urea nitrogen; DOE, dyspnea on exertion; EF, ejection fraction; LVH, left ventricular hypertrophy; PND, paroxysmal nocturnal dyspnea; SOB, shortness of breath.

Cardiac dilatation is observed on chest radiography as an enlarged cardiac silhouette. The point of maximal impulse corresponds to the apex of the LV and is visualized as an external pulsation on the left side of the chest. It is displaced laterally and downward from its normal location at the fifth intercostal space, less than 10 cm from the midsternal line. An S_3 gallop rhythm denotes a third heart sound often heard in close proximity to the second heart sound (closing of the aortic and pulmonary valves) in HF. Rapid filling of the ventricles causes the S_3 sound and, in an adult, usually indicates decreased ventricular compliance. In patients with mitral valve regurgitation, an S_3 heart sound is common and denotes systolic dysfunction and elevated filling pressure. Tachycardia is caused by compensatory increases in sympathetic tone.

Weight gain and edema reflect sodium and water retention resulting from decreased renal perfusion (see Pathogenesis section). As RBF and GFR decrease, a disproportionate amount of BUN may be retained. This phenomenon is termed prerenal azotemia and is detected by an elevated BUN to SCr ratio of greater than 20:1. A.J. has a ratio of greater than 40:1. Prerenal azotemia also can be caused by dehydration and overuse of diuretics. Frequency of urination at night (nocturia) is caused by improved perfusion of the kidney when the patient is lying down.

RIGHT-SIDED HEART FAILURE (RIGHT VENTRICULAR DYSFUNCTION)

The signs and symptoms of right ventricular dysfunction are related either to hypervolemia, valvular disease, or pulmonary HTN. The overall effect is elevation in central venous pressure.

Dependent edema results from increased venous and capillary hydrostatic pressure, causing a redistribution of fluid from the intravascular to interstitial spaces. Ankle and pretibial edema are common findings after prolonged standing or sitting because fluid tends to localize in the dependent portions of the body secondary to gravitational forces. Sacral edema can be present in patients at bed rest. Edema is subjectively quantified on a 1+ (minimal) to 4+ (severe) scale. A.J. has 3+ pitting edema.

Hepatomegaly, hepatic tenderness, and ascites (fluid in the abdomen) arise from hepatic venous congestion and increased portal vein pressure. Metabolism of drugs highly dependent on the liver for elimination can be impaired by both the retrograde venous congestion of the liver from right-sided HF and the decreased arterial perfusion of the liver from left-sided HF. Congestion of the gastrointestinal tract makes the patient anorectic.

Neck vein distension, primarily seen as internal jugular venous distension, denotes an elevated jugular venous pressure.

How high the neck veins are distended while the patient is lying down and how much the patient's head has to be raised before the jugular venous distension disappears gives the clinician a rough estimate of the patient's central venous pressure. Jugular distension in centimeters is measured as the vertical distance from the top of the venous pulsation down to the sternal angle. Neck vein distension of less than 4 cm when the patient is lying with the head elevated at a 45-degree angle is considered normal for an average, healthy adult. Applying pressure to the liver can cause further distension of the neck veins if hepatic venous congestion is present. This phenomenon is termed hepatojugular reflux.

EJECTION FRACTION MEASUREMENT

CASE 14-1, QUESTION 2: Does A.J. have LVSD?

SOB, crackles on auscultation, neck vein distension, edema, and nearly all of A.J.'s other signs and symptoms provide some important clues about the nature of the underlying cardiac abnormalities; however, they are limited in evaluating structural abnormalities. Some of these symptoms can be confused with other disorders, especially reduced exercise intolerance, which is often a gradual process that patients may fail to recognize and report. An enlarged heart on a chest radiograph increases the suspicion of LVSD, but this finding can be absent in some patients with LVSD and present in others with normal LV function. Some patients may be asymptomatic with structural abnormalities.

The most useful method to diagnose HF with LVSD is by measuring the LVEF. All patients with suspected HF should have an EF measured before beginning therapy because the treatment strategies between HFrEF and HFpEF differ. Two-dimensional echocardiography coupled with Doppler flow studies (Doppler echocardiogram) is the diagnostic test of choice for measuring EF. This procedure uses sound waves to visualize and measure ventricular wall thickness, chamber size, valvular function, and pericardial thickness. EF is estimated based on changes in ventricular chamber size between diastole and systole. This method of EF measurement is not as technically accurate as that provided by ventriculography, but the procedure is more comfortable for the patient and the correlation of the measured EF to that of the other methods is acceptable.

Radionuclide left ventriculography (also called a multiple gated acquisition scan) uses radiolabeled technetium as a tracer to measure LV hemodynamics. Although this method is the most accurate measurement of EF, it is moderately invasive because it requires venipuncture and radiation exposure. In addition, radionuclide scanning does not provide information on the architecture of the left ventricle. Magnetic resonance imaging and computed tomography are useful in evaluating ventricular mass but do not provide EF data.

Subsequently, A.J. underwent an echocardiogram. The results were reported as left ventricular hypertrophy (LVH) with mild to moderate depression of EF (30%–40%). Because he has systolic dysfunction and classic congestive signs, he fits the criteria for having congestive HF.

STAGES OF HEART FAILURE AND NEW YORK HEART ASSOCIATION CLASSIFICATION

CASE 14-1, QUESTION 3: What stage of HF does A.J. exhibit according the ACC/AHA criteria? How severe is A.J.'s disability according to the NYHA functional classification of HF?

The ACC/AHA staging scheme and the NYHA functional classification are summarized in Figure 14-1.[4,29]

Because A.J. has symptoms of HF and structural changes in cardiac architecture, he is in ACA/AHA stage C. On admission, A.J. is in NYHA functional class III as evidenced by a need to sleep upright and an inability to undertake even minimal physical activity. It is important to recognize that HF can progress very slowly in some patients and very rapidly in others. A patient with MI could move from stage A to stage C.

PREDISPOSING FACTORS

CASE 14-1, QUESTION 4: What factors contributed to the cause of A.J.'s HF?

Age, HTN, MI, diabetes, tachycardia-induced cardiomyopathy, valvular heart disease, and obesity are well-established major risk factors associated with the development of HF. Other risk factors associated with HF are smoking, excessive intake of alcohol, dyslipidemia, anemia, and chronic kidney disease.[89] There is interest in biochemical and genetic markers that are associated with HF. CAD, and in particular MI, is considered to be the most significant risk factor for HF in the elderly. During the past decades, there has been an increase in the incidence of HF after MI due to the increased survival after MI.[90]

A.J. is especially vulnerable to HF because of his poorly controlled HTN, which increases afterload. HTN can lead to LVH, which is a compensatory response to increased afterload. LVH is associated with a higher risk of HF, especially in younger individuals.[8] The lifetime risk for individuals developing HF with BP of at least 160/90 mm Hg is double that for those with BP less than 140/80 mm Hg.[91]

Preventive strategies directed toward earlier and more aggressive BP control can reduce the incidence of HF by almost 50% and its associated mortality as well.[8]

NONSTEROIDAL ANTIINFLAMMATORY DRUGS AND SODIUM CONTENT

Nonsteroidal antiinflammatory drugs (NSAIDs) exert their antiinflammatory effects by inhibiting prostaglandins. Blocking prostaglandins leads to sodium reabsorption and counteracts the beneficial effects of diuretics and ACEIs. Ibuprofen used for A.J.'s arthritis contributes to sodium overload. Epidemiologic studies indicate that NSAIDs exacerbate HF symptoms, resulting in hospitalizations for HF.[92–94] ACC/AHA practice guidelines recommend avoiding NSAIDs whenever possible in patients with HF.[1]

Another potential source of excess sodium is in IV formulations. Sodium chloride is often used as a diluent for IV drug administration. Some parenteral antibiotics, particularly nafcillin and ticarcillin, have high sodium content. Most prescription and nonprescription drug labels carry a disclosure of sodium content.

A.J.'s HTN and HF are both poorly controlled and he has gained 8 kg. His clinical presentation (orthopnea, dyspnea, SOB, lower extremity edema, elevated jugular venous pressure) clearly indicates fluid overload. This could be a result of high-dose ibuprofen use. His HCTZ should be replaced by a loop diuretic to enhance diuresis. Also, an ACEI should be added to the current regimen for BP control. Once he is euvolemic, the addition of a β-blocker before discharge should be considered. Lowering the dose or preferably discontinuing all NSAIDs might reduce sodium retention and allow ACEI therapy to be more effective. Acetaminophen is an alternative for treating his osteoarthritis.

DIET

It is possible that A.J.'s diet contains a considerable excess of sodium from foods such as canned soups and vegetables, potato chips, or overuse of salt at mealtime. Dietary supplements and sports drinks can also be rich sources of sodium. He should follow a controlled-sodium (2–3 g/day) diet. If salt substitutes are used, he should be warned that they are high in potassium and could cause hyperkalemia if used concurrently with potassium supplements, an aldosterone antagonist, or other potassium-sparing diuretics.

Drug-Induced Heart Failure

CASE 14-1, QUESTION 5: What are the basic mechanisms by which drugs can induce HF, and how can an understanding of these mechanisms be predictive of drugs to avoid in A.J.?

Drug-induced HF is mediated by three mechanisms: inhibition of myocardial contractility (negative inotropic agents and direct toxins), proarrhythmic effects, or expansion of plasma volume (Table 14-5). The latter category includes drugs that act primarily on the kidney (to either alter RBF or increase sodium retention) or those that increase total body sodium and water because of their high sodium content.

The most recognized negative inotropic agents are the β-blockers, which decrease myocardial contractility and slow the HR. Both of these factors can compromise CO. Other well-documented negative inotropic drugs include the nondihydropyridine calcium- channel blockers (verapamil and diltiazem), and some antiarrhythmic agents (disopyramide, flecainide, and dronedarone). The anthracyclines (daunorubicin and doxorubicin) have a direct, dose-related cardiotoxicity that can be minimized by limiting total cumulative doses to 500 mg/m^2.[95,96] (See Chapter 94, Adverse Effects of Chemotherapy and Targeted Agents.) Cocaine and alcohol are cardiotoxins when used chronically in large quantities or after an overdose. Drugs that increase the incidence of arrhythmias will worsen HF if the abnormal rhythm compromises cardiac functioning or output.

Drugs that promote sodium and water retention include NSAIDs, certain antihypertensive drugs, glucocorticoids, androgens, estrogens, and licorice. Weight gain, peripheral and pulmonary edema has been observed in patients with pioglitazone and rosiglitazone.[97] Worsening of HF appears to be dose-dependent and presumed to be at least partly caused by fluid retention. As a consequence, the package inserts for pioglitazone and rosiglitazone recommend they not be administered to patients with NYHA class III or IV HF and that they be used cautiously in earlier stages of HF.[97] Saxagliptin has been also associated with an increased risk of HF hospitalizations. The FDA has initiated an investigation to further evaluate this risk.[98]

TREATMENT

Therapeutic Objectives

CASE 14-1, QUESTION 6: What are the therapeutic goals in treating A.J.?

Table 14-5

Drugs that May Induce Heart Failure

Negative Inotropic Agents	
β-Blockers[a]	Most evident with propranolol or other nonselective agents

	Less with agents with intrinsic sympathomimetic activity (acebutolol, carteolol, pindolol); can also be caused by use of timolol eye drops
Calcium-channel blockers[a]	Verapamil has most negative inotropic and AV-blocking effects; amlodipine has least
Antiarrhythmics	Disopyramide, flecainide, dronedarone
Direct Cardiotoxins	
Cocaine, amphetamines	Overdoses and long-term myopathy
Anthracycline cancer chemotherapeutic drugs	Daunorubicin and doxorubicin (Adriamycin); dose related; keep total cumulative dose <600 mg/m^2
Proarrhythmic Effects	
Class IA, Class III antiarrhythmic drugs	QT interval widening
	Probable torsades de pointes
	HF develops if disturbed rhythm compromises cardiac functioning
Nonantiarrhythmic drugs	Same mechanism as above
(See Crouch et al.[93] for a complete list)	Often associated with drug interactions that inhibit metabolism of the offending drug leading to higher than desired plasma levels
Expansion of Plasma Volume	
Antidiabetics	
	Na retention with pioglitazone and rosiglitazone
NSAID	Prostaglandin inhibition; Na retention
Glucocorticoids, androgens, estrogens	Mineralocorticoid effect; Na retention
Licorice	Aldosterone-like effect; Na retention
Antihypertensive vasodilators (hydralazine, methyldopa, prazosin, minoxidil)	↓Renal blood flow, activation of renin–angiotensin system
Drugs high in Na+	Selected IV cephalosporins and penicillins
	Effervescent or bicarbonate-containing antacids or analgesics
	Also liquid nutrition supplements
Unknown Mechanism	
Tumor necrosis factor antagonists	Multiple case reports of new-onset HF or exacerbation of prior HF with etanercept and infliximab in patients with Crohn’s disease or rheumatoid arthritis

[a] βBlockers and verapamil may be beneficial in diastolic HF. Carvedilol and metoprolol counteract autonomic hyperactivity in systolic dysfunction.

AV, atrioventricular; HF, heart failure; IV, intravenous; Na, sodium; NSAID, nonsteroidal antiinflammatory drugs.

Cure is not a feasible therapeutic objective in patients with most forms of HF, exceptions being patients who are candidates for cardiac transplantation or who have certain forms of viral, alcohol-induced, or tachycardia-induced dilated cardiomyopathy. The immediate objective for A.J. is to provide symptomatic relief by reducing his complaints of SOB and PND, improve sleep quality, and increase exercise tolerance. Parameters to measure success include reduced peripheral and sacral edema, weight loss, slowing of the HR to less than 90 bpm, normalization of BP, reduction of BUN, reduction of heart size on chest radiograph, decreased neck vein distension, and loss of the S_3 heart sound. Long-range goals are to improve A.J.'s EF and quality of life including better tolerance of daily life activities, fewer future hospitalizations, avoidance of side effects of his therapy, and ultimately, an increased survival time. The achievement of these goals depends on the severity of A.J.'s disease, his understanding of his disease, and his adherence to prescribed interventions.

Diuretics

FURODEMIDE AND OTHER LOOP DIURETICS

CASE 14-1, QUESTION 7: Bed rest and a 3-g sodium diet were ordered. The medical team decides to begin furosemide for A.J. What is the rationale for using diuretics and what route, dose, and dosing schedule should be used?

Excessive volume increases the workload of a compromised heart, and diuretics are an integral part of therapy. This is especially true if volume overload is symptomatic (dyspnea) as it is in A.J. Diuretics produce rapid symptomatic improvement. They relieve pulmonary and peripheral edema within hours, whereas the effects of ACEIs, β-blockers, and digoxin take days to months to be fully realized. Diuretics, however, should not be used alone. Even when they are initially successful in controlling symptoms and reducing edema, they are ineffective in maintaining clinical stability for long periods without the addition of other drugs.

More importantly, activation of the RAAS and sympathetic nervous system in response to diuresis could lead to HF progression.

All current guidelines recommend diuretic therapy, both acutely and chronically, if clinical volume overload is evident, but further state that patients without edema can be treated either intermittently or without diuretics.[1] Diuretics used on an intermittent (as-needed) basis are titrated based on changes in weight gain, neck vein distension, peripheral edema, or SOB. Patients with a good understanding of their disease can be instructed to weigh themselves daily and start taking their diuretic if they gain more than 1 to 2 lb in 1 day or 5 lb in 1 week or have leg or abdominal swelling. Diuretics can be withheld as long as patients are at their target dry weight. In other cases, diuretic-free intervals or weekends can be arranged. Even with these options, if the patient has experienced volume overload at some time during the course of his or her disease, either past or present, a diuretic should always be readily available.[99] Despite remarkable initial benefits, vigorous diuretic therapy carries the risk of volume depletion, electrolyte abnormalities, and diminished CO. Abrupt worsening of renal function (increased BUN or SCr) or hypotension indicates the need to temporarily withhold diuretics.

Route of Administration

Furosemide is a commonly used loop diuretic because of clinical experience and low cost. Bumetanide and torsemide are preferred in some settings because of more predictable absorption.[62,63,100,101] Ethacrynic acid, which is also a loop diuretic, is not preferred because of its ototoxic potential. However, unlike other loop diuretics, ethacrynic acid does not contain a sulfonamide moiety, and it is mainly reserved for patients with severe sulfonamide allergies to other loop diuretics.

According to one group of investigators, patients with HF treated with torsemide fare better than those receiving furosemide.[101] During a 1-year open-label trial, patients receiving torsemide were less likely to be admitted to the hospital for HF (17% torsemide vs. 32% furosemide). Admissions for all CV causes were also lower among patients taking torsemide (44%) than patients taking furosemide (59%). Fatigue scores improved to a greater extent in patients treated with torsemide, but no difference was found in the dyspnea score. Torsemide is more expensive than furosemide, and this may be an issue for some patients.

Erratic responses to furosemide are prevalent in persons with severe HF or diminished renal function. Some patients respond promptly and vigorously to small oral doses of furosemide, whereas others require large IV doses to achieve only minimal diuresis. Part of these differences can be explained by the drug's pharmacokinetics.[62,102] Loop diuretics are highly protein bound and have to be actively secreted into the proximal tubular lumen to elicit a response. Tubular secretion of loop diuretics can be compromised in the presence of increased levels of endogenous organic acids due to renal insufficiency and drugs (NSAIDs) that are competing for the same transporters. Also, oral absorption of furosemide is erratic and incomplete, averaging 50% to 60% in healthy subjects and 45% in those with renal failure. When taken with a meal, absorption is delayed, but the total amount absorbed does not differ. There are claims that the absorption and, therefore, effectiveness of furosemide are further diminished in patients with HF attributable to edema of the bowel and decreased splanchnic blood flow. This has been partially refuted by one investigator, who noted an average furosemide bioavailability of 61% in patients with HF, the same as in normal patients.[101] Total absorption in patients with HF varies widely (34%–80%); however, both the rate of absorption and the time to peak urinary excretion are delayed for furosemide and bumetanide.[62,63,103]

The rate and extent of absorption are not only different among individuals, but intraindividual variability also exists. Ingestion of the same brand of furosemide by the same individual on multiple occasions can show up to a threefold difference in bioavailability. These differences are evident with the innovator's brand (Lasix) or generic brands.[104,105]

Dosing

Typically, a patient's treatment is initiated with 20 to 40 mg of oral or IV furosemide given as a single dose and monitored for responsiveness (Table 14-3). If the desired diuresis is not obtained, the dose can be increased in 40- to 80-mg increments to a total daily dose of 160 to 240 mg, usually divided into two or three doses. For torsemide, a usual starting dose is 10 to 20 mg/day, but a ceiling effect is noted in patients with HF at a dosage of 100 to 200 mg/day.[106] Equivalent doses of bumetanide are 0.5 to 1.0 mg once or twice daily, titrated to a maximum of 10 mg daily. Because A.J. is not in acute distress, it could be argued that oral therapy would suffice. The decision, however, is to give a single 40-mg IV dose of furosemide for immediate symptom control. Further increases in the dose or frequency (i.e., twice-daily dosing) of diuretic administration may be required to maintain an active diuresis and sustain weight loss.

Another alternative in hospitalized patients is to administer loop diuretics via continuous infusion. Multiple studies have demonstrated the benefits of continuous infusions compared with intermittent infusions.[107–109] However, the results of these studies have been questioned because of a lack of methodological rigor, and the studies have been underpowered to address the primary end points. Recently, the DOSE trial[110] (Diuretic Optimization Strategies Evaluation) showed no difference in efficacy or safety between intermittent IV bolus or continuous infusion. There are potential benefits of continuous infusion when compared with intermittent bolus dosing. Bolus diuretic dosing can cause a higher rate of diuretic resistance owing to the postdiuretic phenomenon. Continuous IV infusion results in a constant delivery to the tubule, potentially reducing this phenomenon. Additionally, continuous infusions are also associated with a lower incidence of ototoxicity owing to lower peak concentrations. Patients who are candidates for continuous IV infusion should receive a loading dose before infusion to reach steady-state concentrations faster. However, if the patient has received one or more IV boluses within the previous few hours, then an infusion can be started without a loading dose. In case of inadequate response, the loading dose should be repeated and the infusion rate increased. The infusion rate depends on the patient's renal function and response.

ADVERSE EFFECTS

CASE 14-1, QUESTION 8: Examine A.J.'s laboratory values (see Question 1). Does A.J. have any abnormal values? What is the significance of these abnormalities?

Azotemia

A.J. has an elevated BUN (40 mg/dL) but a normal SCr (0.8 mg/dL). Worsening renal function is characterized by an elevation of BUN and creatinine. A disproportionately elevated BUN relative to creatinine is indicative of prerenal azotemia, secondary to poor renal perfusion from HF or overdiuresis. SCr will also rise in some patients with prerenal azotemia, but will quickly return to normal with rehydration.

A.J.'s laboratory values reflect prerenal azotemia. The most probable cause of his azotemia is decreased RBF secondary to decompensated HF. Diuretics should not be withheld and, in fact, judicious diuresis should improve his HF and help lower his BUN. Caution must be exercised because excessive diuresis and volume depletion can cause renal ischemia, leading to true renal damage. If this happens, the SCr also will rise.

Hyponatremia

A low serum sodium of 132 mEq/L is noted. Low serum sodium, however, is not necessarily a sign of overdiuresis. A person may

be significantly overdiuresed with a body deficit of sodium, but if that sodium is lost isotonically, the serum sodium concentration will be normal. Conversely, a person such as A.J. can be hypervolemic, indicating excessive body sodium, but the serum sodium concentration may be normal or even low.

Hyponatremia (low serum sodium concentration) reflects the dilutional effect of extra free water in the plasma. The most common causes of dilutional hyponatremia are excess ADH production or excessive free water intake. Individuals on severely sodium-restricted diets can experience hyponatremia. Likewise, patients given too much diuretic and who are then given salt-free fluids or who have compensatory ADH release can become hyponatremic. Patients with HF or hepatic cirrhosis are more likely to develop diuretic-induced dilutional hyponatremia because of preexisting defects in free water excretion. The exact cause of hyponatremia in A.J. is unknown, but his marginally low serum sodium does not contraindicate continued diuretic therapy. In general, levels of serum sodium concentration less than 120 to 125 mEq/L are associated with adverse events in HF patients; chronic serum sodium concentrations of 130 mEq/L or less are associated with higher morbidity and mortality.[111] Asymptomatic hyponatremia can be treated with water restriction. In the setting of volume depletion, IV administration of normal saline may be effective. Vasopressin receptor antagonists can be used in patients with HF and hypervolemic hyponatremia.

Hypokalemia

A.J. has a serum potassium of 3.2 mEq/L. Hypokalemia is associated with an increased incidence of arrhythmias. Some studies showed increased ectopic activity with serum levels between 3.0 and 3.5 mEq/L.[112–114] It is estimated that the risk of arrhythmias increases by 27% with each 0.5 mEq/L reduction in the plasma potassium concentration less than 3.0 mEq/L.[115]

In chronic HF, potassium abnormalities are commonly seen. The risk of SCD in patients with HF may be lessened by using low doses of diuretics in combination with potassium-sparing agents, with the goal of maintaining serum potassium levels between 4.5 and 5.0 mEq/L.[116]

A.J. will be receiving increased doses of diuretics for the next several days and, therefore, may need additional potassium supplementation to prevent life-threatening hypokalemia. In addition, if he needs digoxin therapy in the future, low serum potassium levels can predispose him to digitalis toxicity. Potassium replacement is warranted for A.J. at this time. Long-term potassium supplementation may not be necessary with concomitant administration of ACEIs. If hypokalemia persists, A.J. can be started on an aldosterone antagonist.

Hypomagnesemia

A.J.'s serum magnesium level is 1.5 mEq/L. Severe hypomagnesemia can lead to somnolence, muscle spasms, a decreased seizure threshold, and cardiac arrhythmias, effects similar to those seen with hypokalemia. Some investigators have claimed that many of the arrhythmias previously ascribed to diuretic-induced hypokalemia were actually caused by diuretic-induced hypomagnesemia.[117] Concurrent hypokalemia and hypomagnesemia can be especially dangerous. A.J. should be given 1 g of magnesium sulfate IV and observed for changes in his magnesium level. If needed, he could be given chronic oral supplements of magnesium.

Hyperuricemia

Increases of 1 to 2 mg/dL in uric acid levels are common during thiazide administration. Rarely, 4- to 5-mg/dL elevations have been reported. A.J.'s uric acid level is 8 mg/dL, which is slightly elevated. It has been proposed that serum uric acid levels may be a valuable prognostic marker in HF patients. One study indicates a graded relationship between serum uric acid and HF survival.[118] In HF, xanthine oxidase is upregulated, which can lead to endothelial dysfunction. Therefore, treatment with allopurinol may improve endothelial function and promote reverse remodeling. The relationship between serum uric acid and CV disease is still controversial, and the guidelines do not recommend the use of xanthine oxidase inhibitors to prevent CV disease. In patients who experience symptomatic hyperuricemia, the addition of allopurinol or other urate lowering agent should be considered (Chapter 45, Gout and Hyperuricemia).

BNP

A.J.'s BNP is elevated (1,365 pg/mL). Various studies evaluating the diagnostic accuracy of BNP and NT-proBNP have used different lower limits to define normal values. The most commonly used plasma concentration to define the upper limit of normal for BNP is 100 pg/mL, with concentrations greater than 400 pg/mL being considered a strong indicator of HF. The age-related NT-proBNP diagnostic upper limit of normal is 125 pg/mL for patients younger than 75 years, and 450 pg/mL for patients older than 75 years of age. If the patient has a level below the upper limit of normal for the respective assay used, then the symptoms are most likely attributable to causes other than HF. In patients with renal impairment, the clearance of these peptides is reduced; therefore, the upper limit of normal is 200 pg/mL for BNP and the corresponding value for NT-proBNP is 1,200 pg/mL.[119] Moreover, concentrations of these biomarkers are influenced by age, sex, obesity, and other cardiac and noncardiac comorbidities. Asymptomatic patients with HF can also present with elevated BNP or NT-proBNP levels. This confounds the accurate interpretation of these markers and makes it challenging to integrate their usefulness into routine clinical practice. Elevated BNP and NT-proBNP have an established utility in ruling out HF in patients who present to the emergency department with SOB.[25] According to the ACC/AHA guidelines, measurement of BNP or NT-proBNP is useful for establishing prognosis or disease severity in chronic HF; however, the role of these biomarkers in reducing morbidity or mortality in HF is not well established. Several NP–guided therapy trials have been published.[120–122] The BNP- or NT-proBNP-guided HF therapy can be useful to achieve GDMT in selected clinically stable patients, but it is unclear if such an approach improves outcome. The Guiding Evidence Based Therapy Using Biomarker Intensified Treatment (GUIDE-IT) study,[123] designed to assess the effects of NP-guided therapy in high risk patients with left ventricular systolic dysfunction did not improve clinical outcomes between biomarker guided treatment strategy vs usual care. It is still not clear when to use biomarkers to adjust HF medications. BNP levels may be elevated in patients receiving ARNI, as BNP is a substrate for neprilysin. Therefore, the 2017 update states that the utility of natriuretic peptide biomarker levels should be cautiously interpreted in patients on ARNI.[6] A.J.'s elevated BNP level, along with his clinical presentation, is indicative of HF exacerbation.

POTASSIUM SUPPLEMENTATION

CASE 14-1, QUESTION 9: The physician gave A.J. one 1-g dose of magnesium sulfate and three 20-mEq doses of potassium chloride IV. This raised his serum magnesium to 2.0 mEq/L and his potassium to 3.9 mEq/L. Should he receive prophylactic magnesium or potassium supplementation? What is an appropriate dose?

At this time A.J. does not need further magnesium replacement, but his serum magnesium level should be measured again after he has received furosemide for a few days. If the level drops again, maintenance therapy with oral magnesium oxide tablets can be started.

A fall in serum potassium concentration can be seen within hours of the first dose of a diuretic, and the maximal fall usually is reached by the end of the first week of treatment. Potassium supplementation is not required in all patients receiving diuretics. They should be monitored frequently in the first few months of diuretic therapy to determine their potassium requirements. Similarly, when diuretics are stopped, it can take several weeks for

---

serum potassium to return to baseline. Therefore, it is possible that A.J.'s admitting potassium level of 3.2 mEq/L reflects the nadir of his response to HCTZ. His initial response to potassium supplementation shows that his hypokalemia will be easily controlled. It might be argued that he should be observed for a few days and not given further supplements; however, because his diuresis is to be increased and if digoxin may later be considered, potassium supplementation is warranted. Long-term potassium supplementation may not be necessary with concomitant administration of ACEIs and aldosterone antagonists. Because A.J. is started on furosemide, HCTZ should be discontinued. If hypokalemia persists, the aldosterone antagonist dose can be uptitrated.

Dose Requirements

It is difficult to predict the dose of potassium chloride that will be required to maintain proper potassium balance. Many patients do well with 20 mEq/day, but it is questionable how many patients need any supplement at all. People with well-documented hypokalemia can require anywhere from 20 to 120 mEq of potassium chloride per day.[124–126] Those patients with disease states associated with high circulating aldosterone levels require doses of potassium in excess of 60 mEq/day. In patients who need long-term potassium supplementation, efforts should be made to increase doses of ACEIs to target doses or maximal tolerated doses, and appropriate addition of an aldosterone antagonist should be considered. However, a few selected patients may still need to take potassium supplementation, despite the addition of an aldosterone antagonist.

MONITORING

CASE 14-1, QUESTION 10: After a single 40-mg IV dose of furosemide, A.J. is begun on 40 mg of furosemide each morning and potassium chloride tablets 20 mEq BID. How should his therapy be monitored?

A.J. needs to be monitored for both an improvement in his HF and for side effects (Tables 14-4 and 14-6). Subjectively, the clinician should monitor for decreased pulmonary distress and an increased exercise tolerance, demonstrating control of HF. Objective monitoring parameters for disease control include weight loss (ideal, 0.5–1 kg/day until ideal dry weight is achieved), a decrease in edema, flattening of neck veins, and disappearance of the S_3 gallop and rales. Because A.J. has HTN, his BP also requires monitoring with a goal to reduce it to <130/80 mm Hg.

Patients are instructed to record their weight each day and are allowed to adjust their diuretic dose based on changes observed. If they are at their ideal "dry weight," they may reduce their dose of diuretic by 50% or even hold one or more doses. If weight increases more than 1 or 2 pounds in a day or 5 pounds per week, edema increases, or SOB returns, the dose of diuretic is temporarily increased.

Dizziness and weakness are subjective indices of volume depletion, hypotension, or potassium loss. Muscle cramps and abdominal pain could indicate rapid changes in electrolyte balance. Objectively, a lowering of BP, especially on standing, and a rising BUN (prerenal azotemia) signify overdiuresis. Serum sodium, potassium, and uric acid should be monitored routinely. Questioning the patient with regard to the onset of diuresis (relative to drug ingestion) and the duration of the diuretic effect helps develop the most convenient and effective schedule for the patient.

REFRACTORY PATIENTS: COMBINATION THERAPY

CASE 14-1, QUESTION 11: If A.J.'s furosemide dose was increased to 80 mg twice a day without much response, what should be the next step?

All loop and thiazide diuretics must reach the tubular lumen to be effective. Because these drugs are highly bound to serum proteins and endogenous organic acids, they cannot enter the tubular lumen by glomerular filtration. For diuresis to begin, they must be transported into the proximal tubule by active secretion from the blood into the tubule. If this active transport is blocked, diuretics will not reach their site of action. This can lead to a diminished diuretic response in patients with either renal insufficiency or decreased RBF associated with decompensated HF. Patients with renal insufficiency or poor RBF often require large doses of diuretics to achieve a desired response. Endogenous organic acids can accumulate during renal insufficiency, avidly binding the drug and preventing its access to the site of action.[62,63] Both the total amount of drug delivered to the tubule and the rate of delivery of the drug to the tubule determine the magnitude of diuretic response elicited.[62,63] This explains why 80 mg of furosemide yields more diuresis than a 40-mg dose and why an IV injection provides a more rapid and vigorous diuresis than an oral dose. Once a threshold concentration (ceiling dose) is achieved within the tubule, higher concentrations produce no greater intensity of effect, but the duration of action may be prolonged.

Many patients exhibit a blunted diuretic response with continued therapy for unknown reasons. Generally, alternative treatment plans are pursued when the dose given approaches the ceiling doses for each drug listed in Table 14-3. Continuous infusions of furosemide (5–15 mg/hour), bumetanide (0.5–1 mg/hour), or torsemide (3 mg/hour) can be more efficacious than intermittent bolus doses in patients with severe HF or renal insufficiency.[62,63,127–129] Even higher doses have been recommended: 0.25 to 1 mg/kg/hour for furosemide, 0.1 mg/kg/hour for bumetanide, and 5 to 20 mg/hour for torsemide.[130] An aggressive protocol of a 100-mg IV bolus of furosemide followed by a continuous IV infusion at a rate of 20 to 40 mg/hour, which is doubled every 12 to 24 hours in unresponsive patients, to a maximal infusion rate of 160 mg/hour to attain a diuresis rate of 100 mL/hour or greater has been described.[131]

In some instances, switching from one loop diuretic to another can overcome the problem.[131] For example, torsemide or bumetanide might work when furosemide fails because of more reliable absorption.[100,101] If this maneuver fails, a combination of diuretics can be tried. The most effective regimens combine drugs that work at two different parts of the tubule.[130] For example, a loop diuretic is used with metolazone, which blocks sodium reabsorption in the distal tubule. Various thiazide diuretics, including chlorthalidone, chlorothiazide, and HCTZ, have been reported to effectively enhance diuresis when combined with a loop diuretic. Triple-therapy regimens of metolazone, a loop diuretic, and an aldosterone antagonist are used to optimize diuresis and electrolyte control.

Most clinicians choose a combination of metolazone plus furosemide or bumetanide. A wide range of metolazone dosages has been investigated.[132] Typically, a low dose of metolazone (2.5–5 mg) is first added to the furosemide therapy. Metolazone can be given intermittently (2–3 times/week or as needed) to relieve congestion. The longer duration of action for metolazone can cause a greater than predicted diuresis and electrolyte loss when combined with a loop diuretic. Thus, careful monitoring of weight, urine output, BP, BUN, potassium, magnesium and SCr is required. Because no parenteral form of metolazone exists, chlorothiazide, at a dose of 500 to 1,000 mg once or twice daily, is an alternative to the thiazide diuretic that can be given intravenously. Although A.J.'s furosemide dose could be increased, metolazone 2.5 mg daily was added. A.J. may also require additional doses of potassium supplementation to avoid hypokalemia with the addition of metolazone.

Angiotensin-Converting Enzyme Inhibitors

AGENTS OF CHOICE

CASE 14-1, QUESTION 12: Along with furosemide, A.J. was started on 10 mg of lisinopril daily. Are there specific ACEIs approved for use in HFrEF patients?

As a general rule, formulary decisions are first based on comparative pharmacologic activity, efficacy, and drug safety. Other factors to consider are labeled (FDA approved) indications, convenience of dosing schedule, and—all else being equal—the cost to the institution and the patient. HTN is the primary indication for all of the ACEIs. Not all ACEIs have an indication for HF.

ACEIs inhibit ACE (also called kinase II), reducing the activation of angiotensin II, a major contributor to the undesired hemodynamic responses to HF. Decreased circulating levels of NE, vasopressin, neurokinins, luteinizing hormone, prostacyclin, and NO also have been noted after administration of ACEIs.

In addition, ACE is responsible for degradation of bradykinin, substance P, and possibly other vasodilatory substances unrelated to angiotensin II. Thus, part of the beneficial effects of ACEIs is caused by the accumulation of bradykinin (Fig. 14-6). After attaching to bradykinin-2 (B_2) receptors, vasodilation is produced by stimulating the production of arachidonic acid metabolites, peroxidases, NO, and endothelium-derived hyperpolarizing factor in the vascular endothelium. In the kidney, bradykinin causes natriuresis through direct tubular effects.

The net effect is that ACEIs regulate the balance between the vasoconstrictive and salt-retentive properties of angiotensin II and the vasodilatory and natriuretic properties of bradykinin. The effects of ACEIs are reduced pulmonary capillary wedge pressure (preload) and lowered SVR and systolic wall stress (afterload). CO increases without an increase in HR. ACEIs promote salt excretion by augmenting RBF and reducing the production of aldosterone and ADH. The beneficial effects on RBF, coupled with the drug's indirect inhibition of aldosterone, lead to a mild diuretic response, a distinct benefit compared to hydralazine.

Vasodilation and diuresis are not the only value of ACEIs in HF. Angiotensin II enhances vascular remodeling, whereas bradykinin impedes this process.[66,133] ACEIs impede ventricular remodeling by blocking the effects of angiotensin II on cardiac myocytes. Evidence as to whether preserving bradykinin levels affects remodeling is inconclusive, although it might attenuate the progressive deposition of collagen during the chronic phase of post-MI cardiac remodeling.

Table 14-6

Monitoring Parameters with Diuretics

↓CHF symptoms (see Table 14-4)
Weight loss or gain; goal is 1- to 2-lb weight loss/day until "ideal weight" achieved[a]
Signs of volume depletion
Weakness
Hypotension, dizziness
Orthostatic changes in BP[b]
↓Urine output
↑BUN[c]
Serum potassium and magnesium (avoid hypokalemia and hypomagnesemia)
↑Uric acid
↑Glucose

[a] Weight loss may be greater during the first few days when significant edema is present

Weight loss may be greater during the first few days when significant edema is present.

[b]A ↓ in systolic BP of 10 to 15 mm Hg or a ↓ in diastolic BP of 5 to 10 mm Hg.

[c]A rising BUN can be caused by either volume depletion from diuretics or poor renal blood flow from poorly controlled HF. Small boluses of 0.9% saline can be given cautiously to differentiate a rising BUN from volume depletion versus poor cardiac output. If volume depletion is present, saline will cause an ↑ in urine output and a ↓ in BUN. However, if the patient has severe HF, the saline could cause pulmonary edema.

BP, blood pressure; BUN, blood urea nitrogen; HF, heart failure.

Individual ACEIs with FDA-labeled approvals for the treatment of HF or LV dysfunction after MI are included in Table 14-7. There is no reason to favor one ACEI over another except in the case of optimizing dosing schedules for patients and trying to use once-daily dosing if possible to improve medication adherence rates.

Numerous placebo-controlled trials have documented the favorable effects of ACEI therapy on hemodynamic variables, clinical status, and symptoms of HF,[134,135] and demonstrated a consistent 20% to 30% relative reduction in HF mortality. ACEI therapy is generally better than other vasodilator regimens, including the hydralazine–nitrate combination or ARBs after considering efficacy and tolerability.

Table 14-7

ACE Inhibitor Dosing in HFrEF

Drug	Available Dosage Form	Initial Dose[a]	Maximal Dose
Captopril[b]	12.5, 25, 50, 100 mg tablets	6.25–12.5 mg TID	100 mg TID
Enalapril[c]	2.5, 5, 10, 20 mg tablets	2.5–5 mg every day	20 mg BID
Fosinopril	10, 20, 40 mg tablets	5–10 mg every day	40 mg every day
Lisinopril	2.5, 5, 10, 20, 40 mg tablets	2.5–5 mg every day	40 mg every day
Quinapril[c]	5, 10, 20, 40 mg tablets	5–10 mg every day	20 mg BID
Perindopril	2, 4, 8 mg tablets	2 mg every day	16 mg every day
Ramipril[c]	1.25, 2.5, 5, 10 mg capsules	1.25–2.5 mg every day	10 mg BID
Trandolapril	1, 2, 4 mg tablets	1 mg every day	8 mg every day

ACE, angiotensin-converting enzyme; BID, 2 times a day; TID, three times a day.

[a] Start with lowest dose to avoid bradycardia, hypotension, or renal dysfunction. All but captopril given every day in the morning at starting doses. Increase dose slowly at 2- to 4-week intervals to assess full effect and tolerance.

[b] Captopril is short acting. Start with a 6.25- or 12.5-mg test dose, then 6.25 to 12.5 mg TID.

[c] Enalapril, quinapril, and ramipril could possibly be given every day instead of BID based on half-life. Benazepril, cilazapril, moexipril, perindopril, ramipril, and trandolapril not labeled for use in heart failure.

Table 14-8 provides a brief summary of the results of the key ACEI HFrEF trials.[18,66,67,135–137] Of the five approved agents, the best evidence for improved survival is available for enalapril in both chronically symptomatic patients (NYHA classes II–IV) and asymptomatic patients with evidence of an impaired EF after an MI.[70,138–140]

The ACC/AHA guidelines recommend selecting an ACEI that has shown reductions in both morbidity and mortality in clinical trials in HFrEF. The following ACEIs are considered first-line options based on clinical trials: captopril, enalapril, fosinopril, lisinopril, perindopril, quinapril, ramipril, or trandolapril.[1,5,6]

Captopril and lisinopril are both active as the parent compound and do not have active metabolites. All other ACEIs are prodrugs that require enzymatic conversion to active metabolites. Captopril has a short duration of action, necessitating three times daily administration in most patients. Although this characteristic may be advantageous when initiating therapy by allowing closer assessment of early side effects, for chronic maintenance, it is preferable to use a drug that can be given either once or twice daily. All other ACEIs meet this criterion. Package insert labeling and common standards of practice have led to twice-daily dosing, especially at higher doses, for enalapril, quinapril, and ramipril.

Table 14-8

Clinical Trials of ACE Inhibitors in HFrEF

Study	Patient Population	ACE Inhibitor	Time Started After MI	Treatment Duration	Outcome
Studies in LV Dysfunction					
CONSENSUS[138]	NYHA IV (n = 253)	Enalapril vs. placebo		1 day–20 months	Decreased mortality and HF
SOLVD-Treatment[136]	NYHA II/III (n = 2,569)	Enalapril vs. placebo		22–55 months	Decreased mortality and HF
V-HeFT II[247]	NYHA II/III (n = 804)	Enalapril vs. hydralazine, isosorbide		0.5–5.7 years	Decreased mortality and sudden death
SOLVD-Prevention	Asymptomatic LV dysfunction (n = 4,228)	Enalapril vs. placebo		14.6–62 months	Decreased mortality and HF hospitalizations
Studies in LV Dysfunction after MI					
SAVE[311]	MI, decreased LV function (n = 2,331)	Captopril vs. placebo	3–16 days	24–60 months	Decreased mortality
CONSENSUS II[312]	MI (n = 6,090)	Enalaprilat/enalapril vs. placebo	24 hours	41–180 days	No change in survival; hypotension with enalaprilat
AIRE[313]	MI and HF (n = 2,006)	Ramipril vs. placebo	3–10 days	>6 months	Decreased mortality
ISIS-4[314]	MI (n >50,000)	Captopril vs. placebo	24 hours	28 days	Decreased mortality
GISSI-3[315]	MI (n = 19,394)	Lisinopril vs. placebo	24 hours	6 weeks	Decreased mortality
TRACE[165]	MI, decreased LV function (n = 1,749)	Trandolapril vs. placebo	3–7 days	24–50 months	Decreased mortality
SMILE[166]	MI (n = 1,556)	Zofenopril vs. placebo	24 hours	6 weeks	Decreased mortality

A.J.'s physician chooses to start lisinopril 10 mg daily based on evidence of clinical efficacy, improved survival, and availability as a generic medication. If there were concerns about hypotension, then captopril would be preferred during the initial 1 to 2 days of initiation therapy to avoid dropping the patient's BP too quickly.

Dose–Response Relationships

CASE 14-1, QUESTION 13: What is the target dose of lisinopril in A.J.? Do all patients need to be titrated to target doses?

Clinical evidence shows a relationship between the degree of improvement in HF symptoms and the dose of drug given. Larger doses are more likely to improve the patient's quality of life and reduce the incidence of hospital stays, but the impact of larger doses on mortality is less clear. At the same time, higher doses are associated with a greater risk of side effects. Based on these principles, proposed recommended starting and maximal doses for the ACEIs are listed in Table 14-7.[1]

The guidelines recommend that ACEIs be initiated at low doses, and titrated to the maximal tolerated target dose. Supporting this principle are the results of the Assessment of Treatment with Lisinopril and Survival trial.[141,142] Lisinopril 2.5 to 5 mg (low dosage) or 32.5 to 35 mg (high dosage) was given to over 3,000 patients. All-cause mortality did not differ significantly between the two groups. In the high-dose group, hospitalizations and the combined end point of death and hospitalization were reduced by 24% ($p = 0.003$) and 12% ($p = 0.002$), respectively. The higher dose was tolerated by 90% of patients assigned this dose.

Despite these recommendations for using the highest tolerated doses, evidence also suggests that lower doses are beneficial. The UK Heart Failure Network Study found that 10 mg of twice-daily enalapril was no more effective than 2.5 mg BID.[143] Mortality, evaluated separately, was 4.2%, 3.3%, and 2.9%, for low (2.5 mg BID), moderate (5 mg BID), and higher (10 mg BID) dosages respectively, and not significantly different. The guidelines recommend prescribing doses that have reduced the risk of CV events in clinical trials and if trial doses cannot be achieved, then lower doses should be used.

For lisinopril, the recommended starting dosage is 2.5 to 5 mg/day. For older patients or those with other risk factors (systolic BP <100 mm Hg, those taking large doses of diuretics, or those with preexisting hyponatremia, hyperkalemia, or renal insufficiency), the starting dose of 2.5 mg/day would be more appropriate. This dose, or an equivalent with one of the other drugs, should be considered if the patient is being started directly on a long-acting drug without prior titration on captopril. For a patient such as A.J. who has already been treated with captopril for 2 days with no evidence of intolerance, a 10-mg dose is appropriate.

The long-term target dosage of lisinopril for A.J. is 40 mg daily. No clear formula exists for deciding how quickly to titrate to this dose. It depends on the degree of reduction in his HF symptoms and side effects, and motivation to take the medication. Whenever dosage adjustments are made, it may take as few as 24 hours for the patient to perceive symptom reduction, but generally full hemodynamic affects are not reached for 1 to 2 months. Hypotension and other side effects are more immediate. A.J. should have his dose reassessed in 1 to 2 weeks to determine whether he can tolerate a dosage increase to 20 mg daily. A SCr and potassium should be ordered at this time to assess the safety of titrating the ACEI. Thereafter, a doubling of the dose could occur every 2 to 4 weeks. Thus, it could take 2 months to titrate upward to 40 mg daily. If A.J.'s symptoms do not improve, but he has no side effects, titration can occur more quickly either by shortening the assessment periods (e.g., every week) or by using larger dose increments.

ANGIOTENSIN RECEPTOR BLOCKERS

CASE 14-1, QUESTION 14: When should an ARB be used in A.J.?

Several clinical trials in HF have shown the therapeutic benefit of ARBs in modifying HF symptoms (Table 14-9).[144–151] A meta-analysis combined data on all-cause mortality and HF-related hospitalizations from a total of 17 clinical trials comparing an ARB with either placebo or an ACEI in patients with HF.[143] ARBs favorably improved exercise tolerance and EF compared with placebo. However, they were not superior to ACEIs in reducing all-cause mortality or hospitalizations for HF.

The first major clinical trial comparing an ARB with an ACEI in patients with HF was the Evaluation of Losartan in the Elderly (ELITE) study.[150] Losartan was compared to captopril. For the primary end point, a sustained increase in renal function decline, the two drugs performed identically with 10.5% of subjects in each group having a greater than 0.3 mg/dL rise in SCr. An unexpected finding was an insignificant trend toward more deaths from all causes in the captopril group (8.7%) compared with losartan (4.8%).

The follow-up ELITE II Trial was specifically designed to test the hypothesis that losartan was superior to captopril in terms of reduction in mortality and morbidity in patients 60 years of age or older.[148] No significant difference was seen in all-cause mortality, sudden death, or all-cause mortality plus hospitalization. Although ARB treatment was not superior to ACEI therapy, it was better tolerated. Specifically, significantly fewer patients experienced cough with the ARB.

The Valsartan Heart Failure Trial (Val-HeFT) was a double-blind, placebo-controlled study to measure the morbidity and mortality HFrEF patients given valsartan.[152] Patients were randomly assigned to receive valsartan or placebo twice daily. There was no significant difference in all-cause mortality between the valsartan group (19.7%) and the control group (19.4%). Nearly 93% of patients in both groups were receiving an ACEI. Dizziness, hypotension, and renal impairment all occurred more frequently in those treated with valsartan.

Further post hoc analysis found that within the 35% of subjects taking the combination of an ACEI and a β-blocker at baseline, the addition of valsartan as a third drug was associated with a trend toward increased morbidity and a statistically significant increase in the combined end point of mortality and morbidity. The overall study results suggested that a combination of valsartan and an ACEI reduces morbidity, but not mortality. More worrisome was the implication that the three-drug combination of valsartan, an ACEI, and a β-blocker adversely affects morbidity and mortality.[155]

The Valsartan in Acute Myocardial Infarction Trial (VALIANT) of stable patients after MI with LV dysfunction was designed to test the hypothesis that valsartan alone and in combination with captopril (ACEI) would improve survival. In VALIANT, 70% of the patients were also receiving β-blockers. All-cause mortality, the primary end point, was identical in all groups. In addition, an increased rate of side effects was seen in the combination ACEI/ARB group. Interestingly, among the subgroup of patients taking β-blockers, no evidence was found of harmful interaction with triple therapy.[153] As a result of the VALIANT trial, the FDA approved the use of valsartan in patients at high risk after a heart attack, and in those with HF.

Table 14-9

Clinical Trials of Angiotensin Receptor Blockers in Heart Failure

Trial	Patient Population	ARB	Treatment Duration	Outcome
ELITE[149]	NYHA II–IV (n = 722) EF ≤40%	Losartan (50 mg every day) or captopril (50 mg TID)	48 weeks	No significant difference observed for the primary end point (persistent renal dysfunction) or the secondary end point (composite of death/HF admissions). Losartan was associated with a lower mortality than captopril.
RESOLVD[151]	NYHA II–IV (n = 768) EF ≤40%	Candesartan (4, 8 or 16 mg), or candesartan (4 mg or 8 mg) + 20 mg enalapril, or 20 mg enalapril	43 weeks	Combination has greater benefits on LV remodeling. No difference in mortality. No difference in NYHA class, QoL, 6-minute walking distance.

ELITEII[150]	NYHA II–IV (n = 3,152) EF ≤40%	Losartan (50 mg every day) or captopril (50 mg TID)	48 weeks	Losartan was not superior to captopril in improving survival, but was significantly better tolerated. A subgroup analysis of ELITE II found a greater risk of death when losartan was used in addition to β-blockers.
Val-Heft[152]	NYHA II–IV (n = 5,010) EF <40%	Valsartan 160 mg BID or placebo BID	23 months	There was no difference in mortality between the two groups. In patients previously receiving both ACEI and a β-blocker (n = 1,610), the risk of death was increased with the addition of valsartan.
CHARM[154] Alternative	NYHA II–IV (n = 2,028) EF ≤40%	Candesartan (32 mg) vs. placebo	34 months	23% reduction in CV mortality or HF hospitalization favoring the candesartan group. More side effects in the candesartan group (hypotension, hyperkalemia, ↑ SCr) vs. placebo.
CHARM[155] Added	NYHA II–IV (n = 2,548) EF ≤40%	Candesartan (32 mg) + ACEI vs. placebo	41 months	15% risk reduction in CV mortality or HF admissions compared with placebo. However, there were more side effects in the candesartan group (hypotension, hyperkalemia, ↑ SCr) vs. placebo.
CHARM[157] Overall	NYHA II–IV (n = 7,599)	Candesartan (32 mg) vs. placebo	38 months	There was no overall difference in primary outcome of all-cause death.

ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; BID, 2 times a day; CV, cardiovascular; EF, ejection fraction; HF, heart failure; LV, left ventricular; NYHA, New York Heart Association; QoL, quality of life; SCr, serum creatinine; TID, three times a day.

The best evidence addressing the efficacy and safety of ARB in HF comes from a series of three investigations known collectively as the Candesartan in Heart Failure

Assessment of Reduction in Morbidity and Mortality (CHARM) trial. The individual components of the CHARM Program are (a) CHARM-Alternative, (b) CHARM-Added, and (c) CHARM-Preserved.[154–156] All three investigations were randomized, double-blind, placebo-controlled trials that enrolled adult patients (>18 years of age) with at least a 4-week history of symptomatic (NYHA class II–IV) HF. Subjects randomly assigned to candesartan were started on 4 mg and titrated to 32 mg once daily, as tolerated. Some standard therapy (diuretics, β-blockers, digoxin, spironolactone, and ACEI) was continued. For all three trials, the primary end point was the combined incidence of CV death, HF hospitalizations, or both. The differences in admission criteria and outcomes among the individual trials are discussed below.

CHARM-Alternative enrolled 2,028 subjects who met all of the inclusion criteria defined above plus two additional criteria: an EF of 40% or less and intolerance of ACEIs (cough, 72%; hypotension, 13%; renal dysfunction, 12%). Thus, subjects in this group received either an ARB alone or placebo without an ACEI. A 23% reduction was found in the primary outcome of CV death, hospital admission for HF, or both in the candesartan group compared with placebo. The overall incidence of drug discontinuations because of adverse events was not statistically different between candesartan and placebo, but there were significantly more reports of symptomatic hypotension, increased creatinine levels, and hyperkalemia in those treated with candesartan (Table 14-10).

The CHARM-Added trial attempted to determine whether the combination of an ACEI plus an ARB offered any clinical advantages compared with an ACEI alone in patients with symptomatic HF with an EF of 40% or less. At baseline, 55% of the patients were treated with β-blockers and 17% with spironolactone. The addition of candesartan to an ACEI and other usual HF treatments led to a 15% relative risk ($p = 0.011$) reduction in the primary outcome of CV death, hospital admission for HF in the combination group compared to the ACEI-alone group. It is interesting to compare the result of the CHARM-Added trial with those of the Val-HeFT study. In Val-HeFT, 93% of the subjects receiving the ARB valsartan were concurrently receiving an ACEI. The combined end point of morbidity and mortality was significantly reduced with combination therapy in Val-HeFT, but mortality alone was not reduced. A trend toward more deaths in the small subgroup receiving the triple combination of a β-blocker with an ACEI and ARB was observed, whereas β-blocker use had no adverse effect in CHARM-Added.

Table 14-10

Adverse Events that Lead to Permanent Drug Discontinuation

Trial	Outcomes	Candesartan (%)	Placebo (%)	p Value
CHARM-Alternative[152]	Any adverse event or laboratory abnormality	21.5	19.3	0.23
	Hypotension	3.7	0.9	<0.0001
	Increased creatinine	6.1	2.7	<0.0001
	Hyperkalemia	1.9	0.3	0.0005
CHARM-Added[153]	Any adverse event or laboratory abnormality			0.0003
	Hypotension	4.5	3.5	0.079
	Increased creatinine	7.8	4.1	0.0001
	Hyperkalemia	3.4	0.7	<0.0001
CHARM-Preserved[154]	Any adverse event or laboratory abnormality	17.8	13.5	0.001
	Hypotension	2.4	1.1	0.006
	Increased creatinine	4.8	2.4	<0.001
	Hyperkalemia	1.5	0.6	0.019
CHARM-Overall[155]	Any adverse event or laboratory abnormality	21	16.7	<0.001
	Hypotension	3.5	1.7	<0.0001
	Increased creatinine	6.2	3.0	<0.0001
	Hyperkalemia	2.2	0.6	<0.0001

The combined results of all three CHARM components (CHARM-Added, CHARM-Alternative, and CHARM-Preserved; see discussion of CHARM-Preserved in Case 14-7, Question 1) were reported in the CHARM-Overall trial.[157] This composite analysis evaluates the benefits of candesartan in symptomatic patients with HF, regardless of LV systolic function. A different primary end point was chosen for the CHARM-Overall analysis: all-cause death. Although the combined results failed to detect a clinically significant reduction in all-cause death between candesartan and placebo (9% reduction; p = 0.32), significant reductions were seen in CV death (12%), hospital admission for HF (21%), and combined CV death or hospital admission for HF (16%), which was the primary end point for the individual trials.

The collective results of the CHARM program reinforce the conclusion that ARBs can reduce morbidity and mortality in symptomatic patients with HFrEF, and they can be safely used in patients who are intolerant of ACEI therapy. Combination therapy (ACEI plus ARB) with concomitant use of β-blockers appears to be beneficial and safe, as long as patients are closely monitored for adverse effects. Current guidelines recommend addition of an aldosterone antagonist over ARB in patients receiving an ACEI and β-blockers.

Because ELITE II failed to demonstrate any survival benefits of losartan 50 mg/day, over captopril 150 mg/day in HFrEF patients, the “Effects of high-dose versus low-dose losartan on clinical outcomes in patients with heart failure” (HEAAL) study was designed to compare the effect of two doses of losartan (50 mg daily versus 150 mg daily) on the combined end point of all-cause mortality and hospitalizations in HFrEF. A median follow-up of 4.7 years showed losartan 150 mg daily reduced the rate of death or HF admission when compared with losartan 50 mg daily. The high-dose group experienced more renal dysfunction, hypotension, and hyperkalemia, although these results did not lead to significantly more treatment discontinuations. Old age, concomitant aldosterone antagonist dose, and baseline levels of potassium and SCr were common predictors of adverse events and resulted in increased mortality among patients who experienced these adverse events. Therefore, dose titrations should be done with close monitoring especially in individuals at high risk of developing adverse events.[158]

In summary, ARB HF trials demonstrate survival benefits in HFrEF in ACEI–intolerant patients or as an add-on therapy to ACEIs and β-blockers. However, current guidelines do not recommend the routine use of triple therapy, and A.J. should not be started on an ARB in addition to his lisinopril. If A.J. develops a cough on lisinopril, he can be switched to an ARB such as candesartan.

Side Effects

ANGIOTENSIN-CONVERTING ENZYME INHIBITOR–INDUCED COUGH

CASE 14-1, QUESTION 15: A.J. presents to the outpatient HF clinic with an annoying productive cough after 6 weeks of lisinopril therapy. His chest examination reveals no evidence of wheezing, with only a few crackles, his neck veins are only minimally elevated over normal, his ankle edema is 1+, and his weight is stable. All laboratory values are normal. Could the cough be a symptom of his HF or is it ACEI–induced? What are the recommendations for managing an ACEI–induced cough?

Cough can be a sign of HF in patients with pulmonary congestion. In extreme cases, patients have “cardiac asthma” with severe air hunger, wheezing, and dyspnea. However, A.J.’s HF is much improved as evidenced by the objective data. The absence of wheezing and no prior history of asthma or smoking make an obstructive airways disease (asthma or chronic obstructive pulmonary disease) unlikely. It is possible that he does have bronchitis, but he does not report having a cold or other respiratory illness

---

preceding the cough. Without other causes, an ACEI–induced cough is most likely.

This side effect occurs with all ACEIs.[159] Cough is a well-established complication of ACEIs and presents as dry and nonproductive; sometimes described as a “tickle in the back of the throat.” This complication can arise within hours of the first dose, or it can present after weeks to months of treatment. Although resolution of the cough usually occurs within 1 to 4 weeks, in some patients it can persist up to 3 months after discontinuation of therapy.

Bradykinin accumulation within the upper airway and decreased metabolism of pro-inflammatory mediators such as substance P or prostaglandins are proposed mechanisms of ACEI–induced cough. These chemicals then act as irritant substances in the airways to increase bronchial reactivity and induce coughing.

Various case reports have found an incidence of cough in 5% to 35% of all patients. The incidence is dose-independent.[160] One investigator found a 5% to 10% incidence in white patients of European descent that rose to nearly 50% in Chinese patients.[161] There may also be a higher incidence in women and black populations.[158]

Because this is a pharmacologic effect rather than an allergic reaction, dose reduction or switching from one ACEI to another is generally not helpful. The only way to definitively diagnose the drug-induced cough is to discontinue therapy. Even then, false-positive results can occur if the patient had a mild case of bronchitis that spontaneously resolved at about the same time that the ACEI was discontinued. If the cough persists after drug discontinuation, other causes should be investigated such as coexisting gastroesophageal reflux disease or allergic rhinitis.

For patients with persistent cough, ARB or hydralazine–isosorbide are safe alternatives. Therefore, A.J. can continue taking lisinopril for another couple of weeks to determine whether the cough will resolve on its own. His symptoms of HF have abated since the initiation of ACEI therapy, and the cough may be no more than an annoyance. He is not at risk of experiencing asthma or other airway problems. If his cough persists, an ARB is probably the best alternative.

OTHER ANGIOTENSIN-CONVERTING ENZYME INHIBITOR AND ANGIOTENSIN RECEPTOR BLOCKER SIDE EFFECTS

Hyperkalemia

CASE 14-1, QUESTION 16: What other side effects of both ACEIs and ARBs need to be monitored? Does changing from an ACEI to an ARB reduce the risk of any of these side effects?

The ACEIs, and ARBs, have the potential to raise serum potassium concentrations via indirect aldosterone inhibition and other neurohormonal actions.[162,163] For most patients, the magnitude of increase in serum potassium concentration from ACEIs and ARBs alone is relatively small, but the risk of developing hyperkalemia is greater if the patient has compromised renal function or advanced HF. Combination therapy of an ACE or ARB with potassium supplements, or potassium-sparing diuretics, further accentuates the risk of hyperkalemia.

Several case reports and case series have reported hyperkalemia and hospitalizations secondary to spironolactone in patients with HF. This became more evident as prescribing patterns for spironolactone dramatically increased after publication of the RALES study.[164] Not only was there a significant increase in the number of prescriptions for spironolactone for patients with HF, but doses higher than those recommended by the clinical trials were often used, especially in patients with evidence of preexisting renal dysfunction. In addition, evidence indicated inadequate monitoring of serum potassium, renal function, and concomitant drug therapy. Although concurrent use of a potassium-wasting diuretic (thiazide or loop diuretic) may counteract potassium retention from spironolactone or other drugs (ACEIs, ARB), it is nearly impossible to predict who will exhibit hypokalemia, hyperkalemia, or remain normokalemic.[165,166] Each patient must be assessed individually for personal response to various drug combinations. Close monitoring of serum potassium is required; potassium levels and renal function should be checked in 3 days and at 1 week after initiation of therapy known to affect potassium and at least monthly for the first 3 months (Table 14-11).

Angioedema

Angioedema (angioneurotic edema) is a severe, potentially life-threatening complication of ACEI treatment.[167–169] Characterized by facial and neck swelling, with obstruction to air flow by laryngeal and bronchial edema, this reaction resembles anaphylaxis. The mechanism of ACEI induction of angioedema is unknown, but is thought to be hypersensitivity to accumulated vasodilating kinins.

Some, but not all, persons with drug-induced angioedema have a history of familial angioedema associated with a genetic defect in their complement system. ACEIs are contraindicated in this population. In one series of case reports, 22% of the reported angioedema reactions occurred within 1 month of starting therapy, with the remaining 77% arising from several months to years later.[168] Black patients and women may have a higher prevalence. Of concern is the observation that ACEI–induced angioedema is often misdiagnosed.[169] It is prudent to avoid all ACEIs in any patient with a history of angioedema from any cause.

Because the mechanism of ACEI–induced angioedema is thought to be caused by kinin accumulation, changing to an ARB might be an option.[170] Several case reports, however, have implicated candesartan, losartan, and valsartan as possible causative agents of angioedema.[167,171–174] In some cases, the subjects had previously experienced angioedema with an ACEI (indicating possible cross-reactivity), whereas others were ACEI–naïve. A small but potential risk for ARB-induced angioedema in patients who are ACEI–intolerant comes from the CHARM-Alternative trial.[154] Of 39 patients with a history of angioedema while taking an ACEI, three experienced angioedema on candesartan, although only one of the three actually discontinued taking candesartan. For now, it is prudent to assess risk–benefit, and ARBs should be used cautiously in the management of patients who have angioedema from ACEIs.

Effects of Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor

Blockers on Kidney Function

As seen in Figure 14-7, glomerular filtration is optimal when intraglomerular pressure is normal. The balance between afferent flow into the glomerulus and efferent flow exiting the glomerulus determines the intraglomerular pressure. A drop in afferent flow or pressure occurring as a result of hypotension, volume loss, hypoalbuminemia, decreased CO, or obstructive lesions such as renal artery stenosis can significantly lower intraglomerular pressure and lead to impaired renal function. Similarly, long-standing HTN can damage glomerular basement membrane capillaries and cause renal insufficiency.

In the case of low-pressure or low-flow states, the RAAS is activated to maintain intraglomerular pressure. A key factor in preserving glomerular pressure is efferent vasoconstriction mediated by angiotensin II. Increased efferent pressure helps to maintain intraglomerular pressure by impeding blood flow out of the glomerulus. When patients with low-pressure states are given ACEIs or ARBs, the protective mechanism of efferent vasoconstriction is inhibited and GFR decreases to a modest degree, resulting in an increase in SCr.

p. 286

Table 14-11

Various Causes of Hyperkalemia and Strategies to Minimize Risk

Cause	Mechanism	Strategies to Minimize Risk
Aldosterone blockers	Decreased levels of aldosterone and subsequent potassium retention.	GFR should be determined and aldosterone antagonist should be avoided if creatinine clearance is <30 mL/minute and baseline serum potassium is >5.0 mEq/L. An initial dose of spironolactone 12.5 mg or eplerenone 25 mg is recommended, after which the dose may be increased to spironolactone 25 mg or eplerenone 50 mg if appropriate. Close monitoring of serum potassium is required; potassium levels and renal function should be checked in 3 days and at 1 week after initiation of therapy and at least monthly for the first 3 months.
RAAS blockade by ACE inhibitors and ARBs Note: risk increases at higher doses (enalapril or lisinopril ≥10 mg/day)	Inhibition of angiotensin II production or receptor binding reduces the delivery of sodium and water to the distal nephron, which, in combination with hypoaldosteronism, promotes	Doses of drugs should be decreased as appropriate.

	hyperkalemia.	
NSAIDs	Inhibit renal prostaglandin synthesis (PGE_2 and PGI_2), resulting in hyporeninemic hypoaldosteronism. Decreased availability of sodium for exchange with potassium at distal tubular sites.	NSAIDs and cyclooxygenase-2 inhibitors should be avoided.
Potassium-sparing diuretics, cyclosporine, tacrolimus, trimethoprim, and heparin	Decreased excretion of potassium.	Close monitoring of serum potassium is required. Doses of drugs known to cause hyperkalemia should be decreased as appropriate.
Patients who have increased dietary potassium intake, use salt substitutes (a rich source of potassium), or take potassium supplements in combination with aldosterone antagonists	In the presence of renal insufficiency, decreased potassium excretion occurs.	Potassium supplements should be discontinued or reduced. Patients should be educated on foods rich in potassium and to avoid salt substitutes.
HF patients with diabetes taking aldosterone antagonists	Hyporeninemic hypoaldosteronism leading to decreased levels of aldosterone and subsequent potassium retention. Insulin deficiency can stimulate the shift of potassium to the extracellular space.	Hyperglycemia should be monitored and appropriate drug therapy should be determined to treat diabetes.
Advanced age, low muscle mass, or renal insufficiency (serum creatinine >1.6 mg/dL)	Impaired release of renin resulting in hypoaldosteronism. SCr may not accurately reflect GFR. Risk of hyperkalemia increases progressively as SCr rises.	GFR should be determined and doses adjusted accordingly.

ACE, angiotensin-converting enzyme; ARBs, angiotensin receptor blockers; GFR, glomerular filtration rate; HF, heart failure; NSAIDs, nonsteroidal antiinflammatory drugs; PGE_2, prostaglandin E_2; PGI_2, prostaglandin I_2; RAAS, renin–angiotensin–aldosterone system.
